Annotation

Spontaneous vegetation succession in disused gravel-sand pits in various regions of the Czech Republic was studied using mostly the space-for-time substitution approach. The main objectives were focused on the variability of vegetation succession in different habitats inside gravel-sand pits over a larger geographical area, the relative importance of local site vs. landscape factors in determining spontaneous vegetation succession, the role of the local species pool, participation of target and undesirable species in the course of spontaneous vegetation succession, and how life-history traits and habitat preferences help predict the establishment of species. In addition, the variability of vegetation development and the relative importance of abiotic site factors influencing spontaneous vegetation succession during early successional stages were studied in a disused gravel-sand pit in the eastern part of the Czech Republic (central Moravia) using permanent plots.

The results demonstrate that vegetation development and differences in abiotic site factors described from one gravel-sand pit, showed similar trends as those from a broad-scale and multi-site study of gravel-sand pits throughout the Czech Republic. The ratio of approximately 1:2:3:4 (time, local site factors, undisclosed and random factors, and landscape factors) express the proportion of environmental factor effects influencing the course of vegetation succession.

Restoration of target vegetation in disused gravel-sand pits by the processes of spontaneous vegetation succession can be an effective and economic alternative to the still prevailing and expensive technical reclamation.

Declaration
I hereby declare that this thesis has been fully worked out by myself and the named co-authors with the use of cited reference.

Introduction
Primary succession is defined as species turnover on barren substrates where severe disturbances have removed most biological activity (Walker & del Moral 2003). Disused pits, where sand and gravel were extracted down to a depth of several metres, provide all of these conditions and represent suitable sites for research on succession, as processes of primary succession hardly ever can be observed elsewhere in the European cultural landscape, except for mining sites (Glenn-Lewin et al. 1992). Despite the fact that such sites are quite frequent in various landscapes, detailed or long-term studies on spontaneous vegetation succession in disused gravel-sand pits are very rare (Borgegård 1990) in contrast to other sites disturbed by extraction, including stone quarries (Ursic et al. 1997, Cullen et al. 1998, Novák & Prach 2003) or dumps and wastes (e.g., Skousen et al. 1994, Kırmer & Mahn 2001, Wiegleb & Felinks 2001, Kovář et al. 2004).

Distinguishing which environmental factors most influence the development of vegetation in disturbed sites is crucial for successful ecosystem restoration. Local site factors and landscape factors act as selective filters of species possessing different traits (Bazzaz 1996, Zobel et al. 1998). Physical and chemical deficiencies or habitat extremes, manifested through texture, stability, temperature, water retention, severe nutrient deficiency, extreme pH values and metal toxicity, are common handicaps of many sites disturbed by mining activities (Marrs & Bradshaw 1993, Bradshaw 2000). However, low water retention, related to texture, and slight nutrient deficiency can be considered as the only limiting abiotic factors of gravel-sand substrates (Lubke et al. 1996). Vegetation change is related to local species pool and governed by both dispersal limitation, and the ability of species to establish and persist (Bakker et al. 1996, Dia et al. 1996, Pywell et al. 2003, Ozinga et al. 2005).

Spontaneous succession often provides desirable target ecosystems and has a large potential as a suitable tool for restoration of many sites disturbed by mining (Prach 2007). Besides its potential contribution to successional theory, an understanding of spontaneous vegetation succession over a landscape scale may be important for promoting natural recovery of degraded ecosystems (Luken 1990, Klötzi and Groot-
jans 2001, Prach et al. 2006). Using a broad-scale experience with succession, we can tentatively predict the rate and direction of succession if we rely upon spontaneous succession or expect to manipulate the spontaneous development in a disturbed site (Glenn-Lewin et al. 1992, Walker & del Moral 2003).

Aims and contents of this study
The main aims of this thesis were: (1) to analyze the spatial-temporal pattern of spontaneous vegetation succession in disused gravel-sand pits over a large geographical scale throughout the Czech Republic, (2) to quantify the effects of environmental factors influencing the course of succession, and (3) to evaluate the potential of spontaneous vegetation succession in restoration programs for particular pits. The following main questions were asked: (1) Does succession run towards (semi-)natural vegetation within a reasonable time? (2) Is succession divergent or convergent inside and among the pits? (3) Are local site or landscape factors more important for the course of succession? (4) Which species traits are correlated with the colonization success of particular species?

For this purpose, the study of disused gravel-sand pits (36) was conducted in various regions of the Czech Republic. The gravel-sand pits comprised stages of different ages, from 1 to 75 years since abandonment, and three habitat types: dry, wet and shallow water. Together, 224 vegetation relevés were recorded with species cover (%) visually estimated using the space-for-time substitution approach (Chapter II–IV).

In Chapter I, the question, which environmental variables determine the course of various successions on broad geographical scales, is answered based on review of 30 studies on vegetation succession, which deal with at least six sites which were spread at least over 10 km². Only seres started on bare ground were considered, i.e. various mining sites, old fields, plantations and pastures, and others (e.g. islands, sand dunes, glaciers). The chapter provides a broader background of the study.

Chapter II presents the results about variability of a particular vegetation succession, i.e. in gravel-sand pits, over a large geographical area. Detailed data about the relative importance of local site (such as water table and soil characteristics) and landscape factors, presence of nearby (semi-) natural plant communities and main land cover categories in the broader surroundings, were evaluated.

In Chapter III, change in the importance of particular ecological groups of species during spontaneous vegetation succession in disused gravel-sand pits is shown. The role of the local species pool, and the participation of target (i.e. grassland, woodland, wetland) and undesirable (i.e. ruderal, alien) species in succession, is evaluated and the implications for spontaneous vegetation succession of disused gravel-sand pits in restoration programs are outlined.

Chapter IV demonstrates that certain life-history traits and habitat preferences are linked with the colonization success of species, occurring in the surrounding vegetation. The colonization success was evaluated separately for different successional stages, i.e. young, middle, late.

Chapter V presents the results of an eight-year monitoring study of spontaneous vegetation succession in 32 permanent research plots in a disused and later restored gravel-sand pit in the eastern part of the Czech Republic (central Moravia). The variability of vegetation development in four different habitats (mesic, wet, shallow water and aquatic), and the relative importance of abiotic factors, such as water table and soil physical and chemical characteristics, were analysed to determine how they influence spontaneous vegetation succession. This study can be seen as a pilot.

The main results of the thesis are summarized in the Conclusions.

Chapter I

Vegetation succession over broad geographical scales: which factors determine the patterns?
Abstract
We reviewed 37 studies on vegetation succession in which the succession started on bare ground, was followed in at least six sites, and where these sites were spatially separated over at least 10 km². The effect of environmental factors, which were explored in at least five studies, on the course of succession was assessed, based on the proportion of significant and non-significant results. Surrounding vegetation, macroclimate, soil moisture, amount of nitrogen and soil texture appeared to have the highest influence on the course of succession. Less influential were the size of a disturbed site, pH, organic matter and phosphorus content. Surrounding vegetation exhibited a significant effect in all cases where this was considered. These results imply that succession cannot be studied without the landscape context. The large-scale approach to succession has the potential to contribute substantially to both the theory of succession and practical applications, especially in restoration ecology.

Keywords: environmental factors, landscape context, restoration ecology, species pool, vegetation succession

Introduction
An enormous number of published studies on succession deal with one or several, more or less comparable sites (e.g., Burrows 1990, Glenn-Lewin et al. 1992, Walker & del Moral 2003). In these studies, succession was often described in remarkable detail, often using experimental manipulation of environmental factors or vegetation itself, thus testing various hypotheses on mechanisms of vegetation change (Tilman 1988, van der Maarel 2005). However, there are not many studies that evaluate succession over broad, i.e. landscape, regional or even continental, scales (van Andel et al. 1993, Walker & del Moral 2003). Those attempts that have been made at this scale are often based on intuitive, not quantitative, comparisons of a high number of seral stages. It is obvious that quantitative studies on succession on a broad geographical scale cannot easily test hypotheses on mechanisms, but they do provide a good opportunity to test hypotheses on pattern. For various reasons, this opportunity has not been appro-
Among the first attempts to describe successional changes in vegetation over larger scales were the studies of early generations of European phytosociologists. By the traditional descriptive approach (using phytosociological relevés) they often analysed many particular sites and then tried to depict intuitively general successional trajectories using formally described plant communities (associations) or dominant species (Ellenberg 1988). These studies provided a useful, though limited overview over vegetation dynamics especially in the case of rapidly changing vegetation such as that on various ruderal sites in urban or industrial habitats (Pyšek & Pyšek 1988). Resulting general schemes were often helpful in urban or landscape planning (Laurie 1979). Advances in computer technology and multivariate techniques enabled researchers to elaborate a large number of vegetation records (Jongman et al. 1987), including those from serial stages. Thus, it seems the number of studies dealing with succession on broad scales has been increasing. Here we review these studies and address the question: Which environmental variables determine the course of succession over broad geographical scales?

**Which series have been studied?**

We have found 37 studies which match the following arbitrarily selected criteria: they deal with at least 6 sites, usually representing different particular seral stages, which were spread over at least 10 km² (Table 1). We considered only series which started on bare ground in which the succession was followed from the very start. Old fields and various mining sites were the most frequently investigated, similarly as among other studies disregarding the scale (Walker & del Moral 2003). Environmental factors considered in the particular studies are listed in Table 1. Those factors, whose influence on the course of succession (defined here as changes in vascular plant species composition) was statistically tested in particular studies, are indicated in the Table 1.

We are aware of the limitations of the data set extracted from the heterogeneous studies which can be hardly mutually compared in a detail. Thus, we concentrate only on the most robust patterns. Causal influences of the environmental factors on the course of succession are differently dealt with in the studies not enabling us to make clear and undoubted generalizations. Therefore only selected aspects are tentatively discussed further.

The studies differed in the number of the sampling plots and in the area covered. It must be mentioned that the same number of sampling plots spread over the same area need not be equally representative in different situations. For example, within a homogenous landscape a small local study can be representative for the whole area, but not so in a heterogenous landscape. Most studies on succession are scaled a priori by human-caused or natural disturbances and sampling follows the pattern. This introduced another component of heterogeneity into the data set. Whether a factor exhibited statistically significant influence on the course of succession (Table 2) depended largely on the range of values dealt with in the particular studies. Generally, there is obviously higher probability of significant influence if the range is broad (Jongman et al. 1987). The studies differed considerably in this regard, thus further weakening the strength of our conclusions. Despite this limitation, the importance of the particular environmental factors is clearly seen from Tables 1 and 2.

**Important environmental factors**

The frequencies in which the factors were reported as having significant or non-significant influence on the course of succession are listed in Table 2, together with the total numbers of studies in which the factors were considered, regardless of whether or not statistics were employed (see Table 1). Time, i.e. successional age, was naturally the most frequent variable to which the course of succession was related, and this factor nearly always exhibited a significant influence on the vegetation pattern. In some studies, the temporal patterns were suppressed by the influence of some abiotic factors if these had a large amplitude (Vaňková & Kovář 2004, Prach et al. 2006). However, the successional age is a major but not only aspect of the temporal dimension. For example, the effect of starting date can also be important. Surrounding vegetation, expressed either as the occurrence of particular vegetation types, land use categories, occurrence of particular species, or dispersal categories around a considered site, had significant influence in all studies where it was considered. Nearly the same is true for macroclimate (temperature, precipitation, altitude and latitude), and for site moisture and nitrogen content among the edaphic factors. Soil structure was also highly influential, especially the content of soil particles such as clay or sand. Organic content, pH and phosphorus had significant influence only in some cases. At least some edaphic factors played a statistically significant role in nearly 80% of studies in which these factors were tested.

Macroclimate and surrounding vegetation can be considered as landscape factors. Edaphic factors, represented mostly by substratum quality, and size of a site represent local site factors. The proportional influence of both groups of factors on the course of succession was only rarely evaluated in a quantitative way. In our study on succession in disused gravel-sand pits, the landscape factors together were responsible for vegetation variability in about 44 %, and the local site factors in 23 % in a CCA analysis. Time contributed about 10 % and the rest was unexplained variability. Soil moisture was the most important of the edaphic factors (Řehounková & Prach 2006).

**Surrounding vegetation and the role of the area of site**

The fact that surrounding vegetation had a significant effect in all cases when it was tested implies that succession is a highly stochastic process if we consider only a particular site without considering the landscape context. Influence of the surrounding vegetation on succession is clearly manifested in species pool, which is determined by macroclimate, vegetation history, and land-use history (Zobel et al. 1998, Settele et al. 1996). Various studies demonstrated the decisive role of sources of diaspores...
Table 1 – Studies on vegetation succession at broad geographical scales and environmental factors considered. In those studies which used rigorous statistics, the factors to obviously influence the course of succession are listed (in italics).

</table>
in the vicinity of a disturbed site and intensity of transport of the diasporas (Fastie 1995, Ursic et al. 1997, Verhagen et al. 2001, Vakólová & Kovář 2004, Dale et al. 2005, Rehounková & Prach 2006). Because sites where succession proceeds can be seen as habitat islands, the theory of island biogeography can be applied to some extent (Bossuyt et al. 2003). The smaller the area of a site the easier, usually, its colonization from close surroundings, and succession usually occurs faster and often directly towards restoration of a previous vegetation than in large sites (Dovčiak et al. 2005).

In large disturbed site, more ruderals have a chance to establish and eventually may arrest or divert succession. In some cases, succession on real islands, either natural or human-made, was studied (Rydin & Borggérård 1988, Rejmánek & Rejmánková 2002). In all those cases, area and isolation were the most important factors, determining especially the number of present species.

It seems that the propagule sources in close vicinity are usually decisive for the establishment of late successional, often target and mostly rather specialized groups of species with lower dispersal ability (Poulin et al. 1999, Novák & Prach 2003). Generalists, which are often present among early successional species, often belong to easily dispersed species, which can colonize a site from a longer distance (Grime 2002). Late successional, dry grassland species colonized basalt quarries with a high probability if they occurred up to the distance of 50 m (Novák & Konvička 2006). Detailed studies of the unique post-eruption landscape of Mt St. Helens revealed the important role of refugia and the distance to the untouched vegetation for re-colonisation, but only up to about 100 m (del Moral et al. 2005). However, in the study conducted in chalk quarries in N England by Jefferson (1984) transport of diasporas of some target species was recorded up to the distance of several kilometers.

**Macrolethal**

The assumption that climate influences succession is trivial (Box 1981). It is, however, difficult to test because of the lack of directly comparable data and conclusions remain largely speculative (Walker & del Moral 2003: 262–266). Increasing precipitation increased stand height and biomass but also participation of alien species in an old-field succession in Tenerife island (Otto et al. 2006). In dry seres, species diversity increased permanently during succession, while it peaked early and then declined in wet seres (Otto et al. 2006). It seems to be a general pattern for extreme vs. moderate site conditions (Peet 1978, Osbornová et al. 1990). Macroclimate determined physiognomy of vegetation and participation of life forms in some studies (Prach 1994, Otto et al. 2006). A study of vegetation succession in 56 disused basalt quarries over a distance of 90 km, where mean annual precipitation varied between 460 and 820 mm, and mean annual temperature between 6.1 and 9.0 °C, found both these variables to be significantly correlated with vegetation pattern (Novák & Prach 2003). Besides the expected direct effects on species establishment, macroclimate influences vegetation succession through the regional species pool (Settele et al. 1996).

Substratum quality

The type of substratum is often reported to determine the course of succession; soil type is important in abandoned fields (Smit & Olff 1998; Gallego Fernández et al. 2004) and substratum texture in industrial and mining deposits (Molyneux 1963; Vaňková & Kovář 2004). Soil moisture (partly influenced by climatic factors), soil nutrients (especially nitrogen), and soil pH are often related to the type of substratum. These factors play a decisive role in driving succession at the local scale (Wilson & Tilman 2002) and often create gradients over large geographical scales (Ellenberg 1988). However, their influence on succession was not often investigated in these scales.

Soil moisture is probably the most important site factor driving succession, but it is difficult to measure it in a comparative way over a large geographical area due to local differences in actual precipitation. Moreover, precipitation itself cannot be always used as a surrogate for site moisture due to topography (but see Otto et al. 2006). Thus, simple categories evaluating site moisture can be used, such as dry, mesic, and wet (Osbornová et al. 1990, Prach et al. 2006). This robust approach may be sufficient even in tentative predictions of succession in landscape or regional scales (Prach et al. 1999). Site moisture often determines participation of different life forms and thus physiognomy of seral stages (Walker & del Moral 2003). This is evident in the participation of woody species, which is usually high in mesic sites but restricted at dry or wet extremes of the moisture gradient (Osbornová et al. 1990, Lichter 1998, Rehounková & Prach 2006).

Substratum pH exhibited significant influence in a half of the cases listed in Table 2, mostly in those that included a broad range of this factor. Both low (Schulz & Wiegleb 2000) and high (Vaňková & Kovář 2004) pH decreased species diversity and slowed down the rate of succession in various industrial and mining deposits. Low pH about 3.5 inhibited colonization by plants in some spoil heaps from brown-coal mining (Schulz & Wiegleb 2000). In an analyses of 15 successional seres on a national scale in the Czech Republic, soil pH was the only significant predictor of successional pattern among 10 soil characteristics tested (K. Prach et al., unpublished).

Amount of nitrogen exhibited significant influence in nearly all studies in which it was tested. High levels of nitrogen usually support competitive herb and grass species (Tilman 1988) which often retard the establishment of woody species (Prach & Pyšek 1994; Smit & Olff 1998).

A study comparing seres running in various habitats: a promising approach

Most of the above-mentioned studies dealt with one type of succession. We have recently developed an approach comparing a number of seres running in various human-disturbed sites over a large region (Prach et al. 2001). Sampling the 15 seres included in the same way enabled a direct robust comparison using rigorous statistics. Multivariate methods revealed that (i) species number and rate of species turnover were positively correlated with soil pH and mean annual temperature, while negatively with altitude and precipitation, and (ii) cover of woody species increased with altitude and precipitation. Thus, soil pH and macroclimate were the most important driving variables in this study (K. Prach et al., unpublished).

Future perspectives

A rigorous comparison of exact data on the course of succession, obtained in many particular sites spread over a broader geographical scale, can help to distinguish between specific and general patterns. It can thus improve successional theory which concerns broad-scale phenomena mostly on intuitive basis only (Walker & del Moral 2003, van der Maarel 2005). The broad-scale approach can help to answer some questions better than detailed local studies. The questions concern especially the differences in the course of succession along large environmental gradients, including climatic ones, divergence vs. convergence, and the influence of different land use and vegetation history. The broad-scale approach may be helpful in studying the expected influence of global change on vegetation pattern (Morecroft et al. 2004).

Because it is practically impossible, in a broad-scale study, to ensure comparativeness among distant sampling sites, this must be at least partly compensated by a high number of such sites, similarly as in traditional phytosociology. The most suitable for such broad-scale studies are abandoned fields that occur in various longitude, latitude and altitudes, and are less heterogeneous than, for example, various mining sites. Thus, using a standardized sampling seems to be easier. Combination of permanent plots and space-for-time substitution (Pickett 1989) is a reasonable approach. As promising, we see the approach when the same local experiments are repeated on a large geographical scale as have been already conducted in some EU projects (van der Putten et al. 2000).

Besides potential contribution to successional theory, knowledge on variability of spontaneous succession over a landscape scale can provide a useful framework to particular restoration projects, if they rely upon spontaneous succession or expect to manipulate the spontaneous development (Luken 1990, Klötzli & Grootjans 2001). For detailed predictions of participation of particular species in succession in a disturbed site we usually need at least a pilot study conducted just in a site, because the high stochasticity and thus often low predictability of species composition in a concrete site (Glenn–Lewin et al. 1992). Very important for restoration practice is to consider the landscape context, regarding especially sources of diaspores of desirable (target), and undesirable (e.g. invasive aliens) species and their chance to establish. Using a broad-scale experience with succession, we can tentatively predict the rate and directions of succession unless a detailed study is conducted usually due to the lack of time or money or both. Various expert systems, which can combine exact detailed data with experiential, often only qualitative knowledge, may be useful in such predictions. The model TELSA was developed to predict vegetation changes in large landscape units (Kurz et al. 2000). By the expert system SUCCESS we can tentatively predict succession in various disturbed sites in the territory of the Czech Republic (Prach et al. 1999). The large-scale approach may be practically exploited in landscape planning strategy. Because of both theoretical and practical contributions, the large-scale approach will probably receive more attention in the future studies on succession.

Chapter II

Spontaneous vegetation succession in disused gravel-sand pits: Role of local site and landscape factors

Abstract

Questions: What is the variability of succession over a large geographical area? What is the relative importance of (1) local site factors and (2) landscape factors in determining spontaneous vegetation succession?

Location: Various regions of the Czech Republic, Central Europe. The regions represent two categories characterized by agrarian lowlands, with a relatively warm and dry climate, and predominant woodland uplands with a relatively cold and wet climate.

Methods: Gravel-sand pits ranged in age from 1–75 years since abandonment. Three types of sites were distinguished: dry, wet and hydric in shallow flooded sites. Vegetation relevés were recorded with species cover (%) visually estimated using the space-for-time substitution approach. Local site factors, such as water table and soil characteristics, and landscape characteristics, namely climatic parameters, presence of nearby (semi-) natural plant communities and main land cover categories in the wider surroundings, were evaluated.

Results: Ordination analyses showed that water table was the most important local site factor influencing the course of spontaneous vegetation succession. Succession was further significantly influenced by soil texture, pH, macroclimate, the presence of some nearby (semi-) natural communities and some land cover categories in the wider surroundings. Spontaneous vegetation succession led to the formation of either shrubby grassland, deciduous woodland, *Alnus* & *Salix* carrs, and tall sedge or reed and *Typha* beds in later stages depending predominantly on the site moisture conditions.

Conclusions: Although the water table was the most influential on the course of vegetation succession, the landscape factors together explained more vegetation variability (44%) than local site factors (23%).

Nomenclature: Kubát et. al. (2002)
Introduction

In contrast to the innumerable papers that describe a particular successional sere in a particular site or several nearby sites, there are surprisingly few studies that have examined one type of spontaneous vegetation succession at large landscape or country scales. Successional studies have been conducted at these scales disturbed by extraction including stone quarries (Ursic et al. 1997; Cullen et al. 1998; Novák & Prach 2003), gravel pits (Borgegård 1990) and dumps and wastes (Skousen et al. 1994; Wieggleb & Felinks 2001). The use of permanent plots is the best method to study long-term changes in vegetation (Bakker et al. 1996). However, the slow rate of the successional process is a difficulty with the large-scale analysis of primary succession (Wiegleb & Felinks 2001). The use of permanent plots is the best method to study long-term changes in vegetation (Bakker et al. 1996). However, the slow rate of the successional process is a difficulty with the large-scale analysis of primary succession on mining deposits (Prach & Pyšek 2001). The alternative space-for-time substitution approach can be used, especially if a high number of comparable sites is available. This robust approach provides an opportunity for analysing successional pathways over a shorter time than by permanent plots (Foster & Tilman 2000). Moreover, the combination of a large number of habitats and the wide range of successional ages covered allows for long-term successional patterns to be distinguished and offers an opportunity to study spontaneous vegetation succession in the landscape context.

Disused pits, where sand and gravel were extracted to a depth of several m, often provide good opportunities to study spontaneous vegetation succession on a bare substratum, which exhibits the characteristics of primary succession (Bradshaw 2000). Distinct seral stages of varying ages are often present. Three main types of sites can usually be distinguished: dry, wet, and hydric in shallow flooded sites (Kondolf 1994).

Sand and gravel extraction occurs on a large scale in the Czech Republic (present mining area 5 400 ha, annual production 35 million tonnes). This production is nearly the same as that of the greatest producer of gravel and sand in Europe, i.e. Germany (400 million tonnes, Kavina 2004), when related to country area and number of inhabitants.

The main objective of this study was to define the course of spontaneous vegetation succession in disused gravel-sand pits throughout the Czech Republic in relation to local site factors and landscape factors. The following main questions were asked: 1. What is the variability of spontaneous vegetation succession in disused gravel-sand pits over a large geographical area? 2. What is the relative importance of local site factors vs landscape factors in determining the spontaneous vegetation succession?

Methods

Study area

The study was conducted in the Czech Republic (48°30’-51°N, 12°-18°50’E) (Fig. 1). The altitude of the studied sites ranged from 170 to 540 m a.s.l. The distance between the northernmost and the southernmost sites was ca. 250 km, and the distance between the easternmost and westernmost sites was ca. 500 km. The pits can usually be distinguished: dry, wet, and hydric in shallow flooded sites (Kondolf 1994). Sand and gravel extraction occurs on a large scale in the Czech Republic (present mining area 5 400 ha, annual production 35 million tonnes). This production is nearly the same as that of the greatest producer of gravel and sand in Europe, i.e. Germany (400 million tonnes, Kavina 2004), when related to country area and number of inhabitants.

The main objective of this study was to define the course of spontaneous vegetation succession in disused gravel-sand pits throughout the Czech Republic in relation to local site factors and landscape factors. The following main questions were asked: 1. What is the variability of spontaneous vegetation succession in disused gravel-sand pits over a large geographical area? 2. What is the relative importance of local site factors vs landscape factors in determining the spontaneous vegetation succession?
land, pastures and woodland according to the Fundamental Base of Geographic Data (ZABAGED®) operated by the Czech Office for Surveying, Mapping and Cadastre.

Climatic data (mean annual temperature, mean annual precipitation) were obtained from the nearest meteorological station operated by the Czech Hydro-meteorological Institute (CHI). Site altitudes were derived from 1:50 000 maps. Soil samples were collected in 2004. Five subsamples of the first 0.3 m below the organic layer of the top soil layer were taken from margins of each relevé and mixed into one pooled sample. Following preliminary results of soil analyses from a pilot study on vegetation succession in disused gravel pits (Rýšavá 2001), the samples were analysed only for the most important characteristics of gravel-sand substrate, i.e. pH and texture (Zbíral 1997). Soil texture was determined by wet sieving and a Fritsch Scanning-Foto-Sedimentograf (www.fritsch.de) for determination of particles smaller than 0.05 mm. Percentage weight of particular soil fractions followed the United States Department of Agriculture (USDA) standard method (gravel: particles > 2 mm, sand: 2–0.05 mm, silt: 0.05–0.002 mm and clay: < 0.002 mm). Water table depth was measured in bore holes on the border of each relevé. The results are based on three measurements conducted annually at the end of July and the beginning of August during 2002–2004. The following sites were arbitrary distinguished in the pits according to site moisture prior to the next analyses: dry (water table > 1 m), wet (water table 0–1 m below the surface) and hydric in shallow flooded sites (0.05–0.2 m above the surface).

Data analysis

Vegetation and environmental data were analysed using multivariate methods in CANOCO version 4.5 (ter Braak & Šmilauer 2002). Species data were logarithmically transformed. A unimodal relationship between species occurrence and time was expected, therefore Detrended Correspondence Analysis (DCA) (length of the gradient of 7.4 SD) and Canonical Correspondence Analysis (CCA) ordinations were used. In DCA analysis, detrending by segments was used and species with a weight of at least 5% were considered. In CCA analyses, inter-samples distance and Hill scaling were used because of data with very long composition gradients. Environmental data were fitted ex post to the DCA ordination axes as passive variables. To separate the effect of locality (i.e. pit), the identifier of relevés situated in sites within the same pit was used as a covariable in analyses. Besides successional age, the following environmental factors were used (Table 1): pH, texture expressed as percentage weight of soil fractions, water table, mean annual temperature, mean annual precipitation, altitude, presence of (semi-) natural communities and proportion of land cover categories.

Forward selection was conducted with all environmental factors (Table 1). Variance inflation factors were below 5, indicating a low correlation of variables (ter Braak & Šmilauer 2002). Subsequent analyses contained only the significant factors (P < 0.05). Within the CCA analyses, combining the factors and covariables followed by a Monte Carlo permutation test (i.e. 999 permutations), allowed for the testing of both the partial effect of environmental factors and the relative importance of local site factors and landscape factors. Marginal effects in CCA were also calculated with CANOCO and tested for significance with Monte-Carlo permutation test (i.e. 999 permutations). The marginal effects of environmental factors denoted the variability explained by given environmental variables without considering other environmental factors, whereas partial effects denoted the variability explained by given environmental variable considering the effects of other environmental factors (covariables).

Results

Species pattern

Three major successional seres (dry (A), wet (B), and hydric in shallow flooded sites (C)) clearly differed as shown in the unconstrained ordination DCA (Fig. 2a). The dry sere was further separated into two subseres: one in lowland (A1) and the other in upland (A2) regions. Obviously, site moisture was the main factor delimiting the seres, while macroclimate delimited subseres only in the case of the dry sites. Significant differences due to macroclimate also appeared only in the case of dry sites in the partial CCA analyses of each sere separately (not presented).

Table 1. Environmental factors considered. The significant factors (see Table 3) are marked in bold.

In total 452 vascular species were recorded, which is ca. 16 % of the total Czech flora. A large group of annual species was typical for initial stages (1–3 a). The dominant species were Centaurea jacea, Trifolium arvense, Digtaria ischaemum, Filago minima and Apera spica-venti in dry sites, Alopecurus aequalis in wet sites and Juncus bulbosus in flooded sites.

Perennial species, such as Phalaris arundinacea, Agrostis capillaris in dry sites, Juncus effusus and Phalaris arundinacea in wet sites and Glyceria fluviatilis in shallow flooded sites, grew along with the annuals (see above) in young stages (4–10 a). Tussilago farfara and Helveria repens dominated in early successional stages, especially on steeper slopes where the substrate was unstable. Open dry grasslands species (e.g. Carex vulgaris) and ruderal species (e.g. Artemisia vulgaris) also occurred in dry sites in this stage.

Perennial grasses and forbs were major dominants in all middle aged stages (11–25 a). Typical species in dry sites were Festuca ovina, Arenella flexuosa, Agrostis capillaris, Calamagrostis epigejos and Phalaris arundinacea in wet sites and Carex bromioides, Pho palustris, ssp. palustris and Deschampsia cespitosa were typical of wet sites. Sedges, such as Carex vesicaria, were frequent in shallow flooded sites. The first dwarf shrubs (e.g. Calluna vulgaris, Rubus fruticosus) appeared in all seres, except flooded sites, in this stage.

Gradually, trees and shrubs expanded into most of the sites after more than 25 a (late successional stages). The proportions of scophytes and nitrophytes increased...
in the herb layer and species typical for open grasslands rapidly decreased. Typical woody species were *Betula pendula* and *Pinus silvestris* in dry sites and *Populus tremula*, *Salix caprea*, *S. cinerea* and *Alnus glutinosa* in wet sites. Different successional trends occurred in relatively extreme sites, i.e. the dry or shallow flooded sites, where dry grassland species (e.g. *Festuca valesiaca*, *F. vaginata* or *Poa angustifolia*) with scattered shrubs (e.g. *Rosa canina*) or, respectively, wetland species (e.g. *Carex vesicaria*) were common.

The oldest successional stages were dominated by trees and shrubs in dry sites located in uplands and wet sites irrespective of geographic area. A relatively rich mixture of woody species (*Quercus robur*, * Sorbus aucuparia* and other woody species already present in the previous stage) was typical of dry sites in uplands. They were accompanied by *Poa nemoralis*, *Dryopteris felix-mas* and *Vaccinium myrtillus* in the herb layer. The woody species composition in wet sites was relatively species-poor in comparison with the former, composed of *Alnus glutinosa* and some willows (e.g. *Salix alba*, *S. purpurea*, *S. viminalis*). A relatively closed herb layer was formed by wetland species in shallow flooded sites, e.g. *Carex acuta* and *C. vesicaria*, *Scirpus sylvaticus*, *Typha latifolia* or *Phragmites australis*. *Arrhenatherum elatius* was the major dominant in dry sites in lowlands. It was accompanied by other abundant grassland species such as *Securigera (Coronilla) varia*, *Festuca vaginata* and *F. valesiaca* and by scattered shrubs represented by *Prunus spinosa*, *Crataegus monogyna* and *Rosa canina*. Woody species such as *Prunus avium* and *Robinia pseudacacia* were also be found in these sites.

**Environmental factors**

Both the DCA and CCA ordinations showed the same general pattern. A high value of species-environment correlations on the first DCA and CCA axes revealed that the significant environmental factors were strong determinants of species variation in the data set (Table 2). Only the DCA graphical outputs are displayed because of the similarity. The CCA analysis showed that 76.3% of variability was explained by the former, composed of *Alnus glutinosa* and some willows (e.g., *Salix alba*, *S. purpurea*, *S. viminalis*). A relatively closed herb layer was formed by wetland species in shallow flooded sites, e.g. *Carex acuta* and *C. vesicaria*, *Scirpus sylvaticus*, *Typha latifolia* or *Phragmites australis*. *Arrhenatherum elatius* was the major dominant in dry sites in lowlands. It was accompanied by other abundant grassland species such as *Securigera (Coronilla) varia*, *Festuca vaginata* and *F. valesiaca* and by scattered shrubs represented by *Prunus spinosa*, *Crataegus monogyna* and *Rosa canina*. Woody species such as *Prunus avium* and *Robinia pseudacacia* were also be found in these sites.

**Discussion**

**General patterns of successions**

Due to the broad moisture gradient, the dry, wet and shallow flooded sites are colonized by different ecological groups of species. Ruderal species with broad ecological amplitudes, which correspond to generalists, are typical for initial and young successional stages in dry sites, while more specialized wetland species occur in the wet and flooded sites of that age (Borgegård 1990, Pietsch 1996). This is also apparent in the vegetation physiognomy (summarized in Table 4). The final physiognomy of spontaneous successional vegetation is usually determined by the proportions of graminoids and woody species. However, some competitive grasses can arrest establishment of woody species for a long time by forming a dense, compact sward (Prach & Pyšek 2001). This is probably the case with *Arrhenatherum elatius*, which is dominant in some dry sites in agrarian lowlands. Flooded sites are usually colonized by specialists (mostly graminoids) forming monodominant stands (Pietsch 1996), which occurred in this study.

Numerous studies have focused on the relative role of site factors and external forces in driving succession (Tilman 1988; Pickett et al. 1987; Walker & del Moral 2003). It is important to know at least the relative importance of particular factors for predicting and possibly manipulating spontaneous successional processes (Walker & del Moral 2003). However, there is a lack of studies exactly evaluating the role of factors at wider geographical and environmental scales. Such studies require a high number of particular sites for a quantitative evaluation, where the same type of succession proceeds. Such sites are not always available. Some recent studies on succession at wider geographical scales provided different results. For example, del Moral et al. (2005) found much more importance of landscape factors, such as proximity of seed sources, than site factors in early primary succession on Mt. St. Helens, while site factors explained more of the variance in understory vegetation in riparian forests (Holl & Crone 2004). It is obvious that the role of the two basic groups of factors depend on the scales and the system studied. Salonen & Setälä (1992) transported substrate between two peatlands in Finland, allowed spontaneous succession to proceed on them and found that the surroundings, manifested in the local species pool, were much more responsible for the vegetation variability than substratum quality.

We expect that the relative importance of site factors and landscape factors are determined by the range of variability of both groups of factors. Obviously, the broader the gradients (such as site moisture), the greater is their responsibility for vegetation variability. The site moisture gradient was very broad in this study, while nutrients and texture were very similar (Rehounková unpubl.). The landscape factors were manifested in the large geographical area considered, and under diverse

**Environmental factors**

Both the DCA and CCA ordinations showed the same general pattern. A high value of species-environment correlations on the first DCA and CCA axes revealed that the significant environmental factors were strong determinants of species variation in the data set (Table 2). Only the DCA graphical outputs are displayed because of the similarity. The CCA analysis showed that 76.3% of variability was explained by the former, composed of *Alnus glutinosa* and some willows (e.g., *Salix alba*, *S. purpurea*, *S. viminalis*). A relatively closed herb layer was formed by wetland species in shallow flooded sites, e.g. *Carex acuta* and *C. vesicaria*, *Scirpus sylvaticus*, *Typha latifolia* or *Phragmites australis*. *Arrhenatherum elatius* was the major dominant in dry sites in lowlands. It was accompanied by other abundant grassland species such as *Securigera (Coronilla) varia*, *Festuca vaginata* and *F. valesiaca* and by scattered shrubs represented by *Prunus spinosa*, *Crataegus monogyna* and *Rosa canina*. Woody species such as *Prunus avium* and *Robinia pseudacacia* were also be found in these sites.

**Discussion**

**General patterns of successions**

Due to the broad moisture gradient, the dry, wet and shallow flooded sites are colonized by different ecological groups of species. Ruderal species with broad ecological amplitudes, which correspond to generalists, are typical for initial and young successional stages in dry sites, while more specialized wetland species occur in the wet and flooded sites of that age (Borgegård 1990, Pietsch 1996). This is also apparent in the vegetation physiognomy (summarized in Table 4). The final physiognomy of spontaneous successional vegetation is usually determined by the proportions of graminoids and woody species. However, some competitive grasses can arrest establishment of woody species for a long time by forming a dense, compact sward (Prach & Pyšek 2001). This is probably the case with *Arrhenatherum elatius*, which is dominant in some dry sites in agrarian lowlands. Flooded sites are usually colonized by specialists (mostly graminoids) forming monodominant stands (Pietsch 1996), which occurred in this study.

Numerous studies have focused on the relative role of site factors and external forces in driving succession (Tilman 1988; Pickett et al. 1987; Walker & del Moral 2003). It is important to know at least the relative importance of particular factors for predicting and possibly manipulating spontaneous successional processes (Walker & del Moral 2003). However, there is a lack of studies exactly evaluating the role of factors at wider geographical and environmental scales. Such studies require a high number of particular sites for a quantitative evaluation, where the same type of succession proceeds. Such sites are not always available. Some recent studies on succession at wider geographical scales provided different results. For example, del Moral et al. (2005) found much more importance of landscape factors, such as proximity of seed sources, than site factors in early primary succession on Mt. St. Helens, while site factors explained more of the variance in understory vegetation in riparian forests (Holl & Crone 2004). It is obvious that the role of the two basic groups of factors depend on the scales and the system studied. Salonen & Setälä (1992) transported substrate between two peatlands in Finland, allowed spontaneous succession to proceed on them and found that the surroundings, manifested in the local species pool, were much more responsible for the vegetation variability than substratum quality.

We expect that the relative importance of site factors and landscape factors are determined by the range of variability of both groups of factors. Obviously, the broader the gradients (such as site moisture), the greater is their responsibility for vegetation variability. The site moisture gradient was very broad in this study, while nutrients and texture were very similar (Rehounková unpubl.). The landscape factors were manifested in the large geographical area considered, and under diverse
Fig. 2a. DCA ordination of species and samples. The direction of succession in particular seres are shown using centroids (triangle) for each age group. Increasing size of the symbols corresponds to increasing age: initial (1–3 yr), young (4–10 yr), middle (11–25 yr), late (26–40 yr), old (> 40 yr). Seres are indicated with underlined letters: A – dry sere in dry and warm regions, A2 – dry sere in wet and cold regions, B – wet sere in both regions, C – shallow water sere in both region. The species with highest abundance in different age groups include: Carex vesicaria, Alopecurus aequalis, Festuca vaginata, Agrostis capillaris, Avenella flexuosa, Conyza canadensis, Elytrigia repens, Deschampsia cespitosa, Digitalis lanata, Juncus bulbosus, Juncus articulatus, Hieracium pilosella, Holcus lanatus, Juniperus communis, Juniperus communis, Lyceum europaeus, Paeonia officinalis, Potamogeton natans, Poa bulbosa, Ranunculus repens, Rumex acetosella, Salix alba, Salix viminalis, Viola riviniana, Vetria riviniana, Xerophyllum tenax.

land cover. In spite of many limitations, the ratio of ca. 1:2:3:4 (time, local site factors, undisclosed and random factors, landscape factors) may be tentatively expected in other sets of seral stages of a similar character.

Surprisingly, time was responsible for only ca. 10% of the vegetation variability in our data set. This is less than in other studies covering such a range of successional ages (e.g. Holl 2002). It is likely that the broad environmental gradients covered in our study partly masked the role of time.

Particular environmental factors

In this study, the surrounding vegetation was very important factor affecting the process of colonization of man-made sites. A similar conclusion has been reported from gravel-sand pits (Borgegård 1990), dumps (Ninot et al. 2001), stone quarries (Novák & Prach 2003), newly established wetlands (Reinartz & Warne 1993; Edwards & Profitt 2001) and abandoned fields (Olsson 1987; Pickett et al. 2001). Climatic factors are also important for driving succession, because these influence the respective regional species pool and can physiologically constrain, among others, the participation of woody species in sere stages in central Europe (Novák & Prach 2003; Ruprecht 2006). The influence of altitude has been referred to as an environmental factor modulating the general distribution pattern of vegetation through macroclimatic effects (Gallego Fernández et al. 2004). In this study, it seems that higher precipitation and lower evapotranspiration at the higher altitudes probably compensate for the lower water table of dry sites and, therefore, such sites provide suitable environmental conditions for the establishment of woody species. Woody species, which dominate the older stages within the dry sites in uplands and in all wet sites in the studied pits, started sooner and expanded faster under the moderate environmental conditions, while they were rare or absent in extreme (very dry or flooded) sites. This corresponds to evidence from other studies on the environmental factors determining the establishment of woody species in man-made sites (Christensen & Peet 1984; Prach & Pyšek 1994) besides the local species pool, competition for the herb layer and grazing (Olsson 1987; Pickett et al. 2001).

The mean water table depth of ca. 1 m seems to be critical for species requiring wet sites (Elgersma 1998). This agrees with studies in other excavated sites where soil
moisture was considered to be the most important site factor determining the establishment and growth of vegetation (Brenner et al. 1984, Fierro et al. 1999).

Soil pH increased with age, which is different from a successional study in gravel-sand pits in Sweden (Borgegård 1990), and decreased with altitude. These trends are also reflected in the change in the vegetation pattern from the prevailing neutral species of dry grasslands in agrarian lowlands to the acidophilous woodland species in forested uplands participating in the succession (Ellenberg et al. 1991). This was probably due to the combined effect of different sedimentation in lowlands (Carling & Pets 1992) and macroclimate.

Decreasing grain size distribution from sites located in humid uplands towards the sites in dry lowlands probably reflects the general trend of decreasing size of river sediments downstream (Carling & Pets 1992).

Conclusions

At the country scale, spontaneous vegetation succession led to the formation of either (A1) shrubby grassland in dry sites in lowlands; (A2) deciduous woodland in dry sites in uplands; (B) Alnus and Salix carrs in wet sites, irrespective of region, or (C) tall sedge, or reed and Jptha beds in shallow flooded sites irrespective of region (Table 4). Except for some dry sites in lowlands, where the alien species Robinia pseudacacia may expand, the succession proceeds towards stabilized, (semi-) natural vegetation within 40 years (Table 4). Site moisture was the most influential on the course of succession. The vegetation pattern was farther significantly influenced by the following studied factors: pH and the proportions of silt and gravel among local site factors, altitude, mean annual temperature, mean annual precipitation, presence of some vegetation types up to 100 m from a sampling site, and prevailing land cover up to 1 km from a pit. The landscape factors combined were more influential (44 %) than local site factors (23 %) in affecting the course of vegetation succession.

Acknowledgements

The study was supported by the following grants: MSM 6007655801, AVOZ 6005908, GA CR 206/02/0617, Fund for Development of Universities 1839 and Foundation The Talent of Josef, Marie and Zdeňka Hlávka. We thank Karen Holl, Anna Martha Elgersma and Sandor Bartha for their valuable comments on the manuscript, Jan Lepš for his advice in statistics and Keith Edwards for language revision.

Spontaneous vegetation succession in gravel-sand pits: a potential for restoration

Restoration Ecology [in press]
Spontaneous vegetation succession in gravel-sand pits: a potential for restoration

Abstract

Vegetation variability, the participation of target and undesirable species and the role of local species pool were studied in the course of spontaneous succession in disused gravel-sand pits. The study was conducted in various regions of the Czech Republic, Central Europe. The regions represented either agrarian lowlands with a relatively warm and dry climate, or mostly woodland uplands with a relatively cold and wet climate. The gravel-sand pits (36) comprised stages of different age from 1 to 75 years since abandonment. Three types of environments were distinguished: dry, wet, and hydric in shallow flooded sites. Altogether, 224 vegetation samples were recorded with species cover (%) visually estimated. Species affinity to different vegetation types was assessed in each sample based on the species cover. Local site factors, such as water table and soil characteristics, and landscape characteristics, namely climatic parameters, presence of nearby (semi-) natural plant communities and main landcover categories in the broader surroundings, were evaluated as well as the participation of target (grassland, woodland, and wetland) and undesirable (ruderal, alien) species. Ordination analyses showed that vegetation succession led to target grassland, wetland, or woodland vegetation depending on local site factors and the presence of (semi-) natural vegetation in the surroundings (local species pool). Restoration of target vegetation in disused gravel-sand pits by processes of spontaneous succession can be possible and successful in about 20 yr, especially if (semi-) natural vegetation exists in the surroundings. The invasion of the alien tree *Robinia pseudacacia* must be taken into consideration within the dry sites in lowlands.

Introduction

The restoration of land damaged by gravel-sand mining is increasingly considered in various countries. It has appeared as an important problem also in the Czech
Republic, where this study was conducted. In this country, about 5 400 ha have been affected by gravel-sand mining. Production of gravel-sand reaches 3.5 t per capita, which is slightly less than the production of the largest European producer, i.e. Germany, which produces 4.8 t per capita (Kavina 2004). The Czech land reclamation policies require that disused mining sites must be reclaimed to their previous use, i.e. to forests or agricultural use. Forest use is often interpreted as planting with conifers, mostly Scots pine (*Pinus sylvestris*). State forest agencies are often required to create plantations that generate economic benefit through timber production. Agrarian use is interpreted mostly as conversion to arable land. Reclamation to a water body is performed in sites where the gravel-sand was mined to below the groundwater table. The estimated average costs for reclamation of 1 ha is about 1.5 million Czech crowns (i.e. about US$60 000) depending on the type of reclamation (Kavina 2004). Thus, gravel-sand pit restoration is often a good business for reclamation companies, disregarding real necessity.

This paper contributes to the neglected topic of using spontaneous vegetation succession in ecological restoration of disused gravel-sand pits. At present, spontaneous succession is not considered as a regular rehabilitation method for post-mining landscapes; current thinking is still technocratic. We assumed that the minimum intervention inherent in spontaneous succession in the case of suitable site conditions, especially if the site is surrounded by (semi-) natural vegetation, could be an effective and economical option for establishing vegetation as found in other disused mining sites (Prach & Pylek 2000, Wiegble & Feliniks 2001). In a previous study (Řehounková & Prach 2006) four particular seres were distinguished based on species data. Besides species, this study included ecological groups of species that are often sufficient for restoration practice (Voigt & Perner 2004). The groups were defined by affinity of species to distinct vegetation types, using the fidelity concept (Chytrý & Tichý 2003).

The questions addressed in this paper are: How does the participation of ecological groups of species change during spontaneous succession? What is the influence of the surrounding (semi-) natural vegetation on the course of vegetation succession? How successful were target and undesirable species, especially in relation to their presence in the surroundings? Is spontaneous succession really a suitable option for restoration of disused gravel-sand pits?

**Methods**

**Study area**

The study was conducted in 36 sand-gravel pits across the Czech Republic, Central Europe (49°30’–51°N, 12°–18°E). The altitude of the studied sites ranged from 170 to 540 m a.s.l. The distance between the northernmost and the southernmost sites was ca. 250 km, and the distance between the easternmost and westernmost sites was ca. 500 km. The pits can be classified according to their location in either (a) lowlands (altitude 170–250 m a.s.l.) having a relatively warm and dry climate (mean annual temperature 8.0–9.2 °C, precipitation 480–550 mm) and used mostly for agrarian purposes, or (b) uplands (altitude 255–540 m a.s.l.) having a relatively cold and wet climate (mean annual temperature 6.8–7.9 °C, mean annual precipitation 551–780 mm) and dominated by woodland. All of the pits were established on sand and gravel deposits originated from aeolian and fluvial processes during the Quaternary period (Kavina 2004). The area of the individual pits ranged from 1 to 95 ha.

**Sampling**

The gravel-sand pits were surveyed from 2002 to 2004. The history of each pit was reconstructed on the basis of official records from mining companies and county authorities or by interviewing local administrators. The pits and representative sites in each of them were selected using the following criteria: (1) the existence of sufficiently large, spontaneously re-vegetated sites, (2) the year of abandonment was known, (3) no evidence of allochthonous substrates, and (4) no evident additional disturbance. The period since abandonment (age) ranged from 1 to 75 yr. The following successional stages were arbitrarily designated: initial (1–3 yr), young (4–10 yr), middle (11–25 yr), late (26–40 yr) and old (>41 yr). All sufficiently large and homogenous sites were sampled, avoiding those of unclear history. Phytosociological relevés 5 m x 5 m were recorded in the centre of each of the sites. In this way, 224 relevés were obtained with a mean number of six relevés per pit. Percent cover for vascular plant species and total cover of bryophytes and lichens were estimated in each relevé. The inclination of all sites where the relevés were recorded was only 0°–5°. Thus, inclination was not considered further as an explanatory variable. The presence of (semi-) natural vegetation, namely dry grasslands, forest fringes, pastures, wetlands, and woods was recorded up to 100 m from a relevé. The total list of species present in these vegetation types was made. The percentage of the main land cover categories was estimated up to 1 km from the margin of a pit. The following categories were considered: arable land, urban land, dry grasslands, wet grasslands, pastures and woodland according to the Fundamental Base of Geographic Data (ZABAGED®) operated by the Czech Office for Surveying, Mapping and Cadastre.

Climate data (mean annual temperature and precipitation) were obtained from the nearest meteorological station operated by the Czech Hydrometeorological Institute. Site altitudes were derived from 1:50 000 maps. Soil samples were collected in 2004. Five subsamples of the first 0.3 m below the organic top soil layer were taken from each relevé and mixed into one pooled sample. Based on preliminary results of soil analyses from a pilot study on vegetation succession in disused gravel-sand pits (Ryšavá 2001), the samples were analysed only for the most important characteristics of gravel-sand substrate, i.e. pH and texture (Zbiraj 1997). Soil texture was determined by wet sieving and a Fritsch Scanning-Foto-Sedimentograf for determination of particles smaller than 0.05 mm. Percent weight of particular soil fractions followed the United States Department of Agriculture standard method (gravel: particles >2 mm, sand: 2–0.05 mm, silt: 0.05–0.002 mm and clay: < 0.002 mm). Water table depth was measured in bore holes on the border of each relevé. The results are based on three measurements conducted annually at the end of July and the beginning of August in all three study years. The following sites were arbitrarily distinguished in...
the pits according to site moisture prior to data analysis: dry (water table deeper than 1 m), wet (water table 0–1 m below the surface) and hydric in shallow flooded sites (0.05–0.2 m above the surface).

**Data analyses**

Vegetation and environmental data were analyzed using multivariate methods in CANOCO version 4.5 (ter Braak & Šmilauer 2002). Determination of alien species follows Pyšek et al. (2002). Species were classified according to their affinity, called fidelity, to grassland, ruderal, woodland and wetland vegetation according to Chytrý & Tichý (2003) and then, by the same approach, to particular vegetation type listed in Fig. 1. Total species cover, representing each vegetation type, was calculated for each relevé. In this way, data were obtained on vegetation types used in a DCA as ‘species’ data (ter Braak & Šmilauer 2002).

A unimodal relationship between species occurrence and time was expected, therefore DCA (length of the gradient of 4.9 SD) and CCA ordinations were used. In DCA analysis, detrending by segments was used and species with a weight of at least 5% were considered. In CCA analyses, inter-sample distance and Hill scaling were used, because of data with long composition gradients. Environmental data were fitted as passive variables (ter Braak & Šmilauer 2002). To separate the effect of locality (i.e. pit), the identification of relevé situated in the same sites within the same pit was used as a covariable in the analyses. Besides successional age, the following environmental factors were used (Table 1): pH, texture determined by percent weight of soil fractions, water table, mean annual temperature, mean annual precipitation, altitude, presence of (semi-) natural vegetation, and percentage of land cover categories in the surroundings. Forward selection was conducted with all environmental factors using the Monte-Carlo permutation test with 999 permutations.

DCA species response curves of target and undesirable species groups were performed using Canodraw (ter Braak & Šmilauer 2002). The effect of fertile black locust (*Robinia pseudacacia*), present up to a distance of 100 m from a sampling site, on particular vegetation types (initial, young, middle, late, old) in disused gravel-sand pits in lowlands (A1), was tested by CCA using the Monte-Carlo permutation test with 999 permutations. The occurrence of *R. pseudacacia* in other seres (A2, B, C) and in their surroundings was very rare, thus it was not tested.

**Results**

### Vegetation pattern and environmental factors

The ordination analyses distinguished four particular seres: dry in lowlands (A1), dry in uplands (A2), wet (B) and flooded (C), with the latter two disregarding the regions. The groups of species belonging to different vegetation types, i.e. grassland, woodland, wetland and ruderal, used in the ordination are given in Fig. 1. Site moisture was the main factor delimiting the seres, while macroclimate separated sub-seres only in the case of dry sites.

The dry sere in lowlands (A1) started with annual and perennial thermophilous ruderal species. Some species typical of late successional, open herbaceous, open sand, and dry grassland vegetation on shallow soils, e.g. grey hair-grass (*Corynephorus canescens*), occurred already in the initial stages. The course of succession in the dry sites in lowlands ran towards two different vegetation types: dry shrubby grasslands or *Robinia* groves.

The initial stages (1–3 yrs) of the dry sub-sere in uplands (A2) were dominated by perennial mesophilous ruderal and grassland species. There was a gradual transition from grassland to woodland in this sub-sere. Broad-leaved deciduous forests are the most distinguished vegetation type of late stages (>41 yrs) in these dry sites in uplands.

The wet sere (B) started with nonruderal wet grassland species. This sere changed over time from wet grassland to wet woodland. The old stages (>41 yrs) were represented by alder and willow carrs.

The initial stages (1–3 yrs) of the hydric sere in shallow flooded sites (C) were dominated by the nonruderal annual species of wet eutrophic soils. Species typical of reed and tall-sedge beds dominated in the old stages (>41 yrs).

Because the DCA ($\lambda_1: 0.788, \lambda_2: 0.667$) and CCA ($\lambda_1: 0.654, \lambda_2: 0.562$) showed basically the same pattern, only DCA graphical outputs are displayed (Fig. 1). The environmental factors, which were significantly correlated with the ordination axes, are indicated in bold in Tab. 1. The occurrence of dry grassland, wet grassland, and woodland species in disused gravel-sand pits was clearly associated with the presence of respective vegetation types in the surroundings of a sampling site (Table 1).

Fig. 1. DCA ordination of species groups and samples. Polygons enclose the vegetation records of initial (1–3 yrs, dashed line) and old (> 41 yr, solid line) stages of each sere. Seres: A1 – dry in lowlands, A2 – dry in uplands, B – wet, C – shallow flooded. The inset diagram shows significant environmental variables ($P < 0.001$, see Table 1) fitted ex post as passive variables. The vegetation types with weight > 5% were considered:

Grassland: Gd – open herbaceous grassland on shallow soils, Ge – close dry grassland, Gf – dry shrubby grassland, Gg – open sand grassland with Corynephorus canescens, Gh – mesic grassland, Gi – Nardus grassland & heathland, Gj – wet grassland

Woodland: Wk – Robinia grove, Wl – coniferous forest, Wm – broad-leaved deciduous forest, Wn – riverine willow scrub and willow-poplar forest, Wo – alder and willow carrs

Wetland: Hp – annual vegetation of wet eutrophic soils, Hq – reed and tall-sedge bed

Ruderal vegetation: Ra – with prevailing annuals, Rb – with prevailing perennials on drier sites, Rc – with prevailing perennials on mesic and wet sites

**Target and undesirable groups of species**

Changes in the proportion of target (grassland, woodland and wetland) and undesirable (ruderal and alien) groups of species during succession in each sere are shown in Fig. 2. The importance of grassland species decreased in most sites, except dry sites in lowlands, during succession, while woodland species increased. The importance of wetland species in shallow flooded sites remained stable for 50 years, in wet sites they decreased rapidly in the course of succession due to the expansion of woodland species (Fig. 2). The importance of undesirable species groups (ruderals, aliens) decreased in the majority of sites, except the alien group of species in dry sites in lowlands; this reflects the expansion of *Robinia pseudacacia* in some sites. The participation of ruderal and alien species was much lower in wet than in dry sites.

Nearly three-quarters of target grassland and woodland species, occurring in the surroundings, appeared in the pits (Fig. 3). Wetland species were the most successful group of target species, because nearly 90% expanded into the pits from the surroundings, and some others migrated even from a longer distance. Only about 50% of ruderal species expanded from the surroundings. However, the least desirable alien species were rather successful and about three-quarters expanded from the surroundings into the pits.

The presence of mature *R. pseudacacia* trees in the surroundings (up to 100 m from a sampling site) had a significant effect (CCA, F=2.012, P<0.05, λ 1: 0.571, λ 2: 0.456) on the course of succession in dry sites in lowlands (Fig. 4). The direction of succession was very similar only in the initial and young stages (1–10 yrs) irrespective of the presence of fertile *R. pseudacacia* in the surroundings. However, the differences between dry sites with and without *R. pseudacacia* in the surroundings increased with increasing successional age. In the former sites, the old stages were formed by *Robinia* groves accompanied by nitrophilous species such as small balsam (*Impatiens parviflora*), greater celandine (*Chelidonium majus*), herb bennet (*Geum urbanum*) and herb robert (*Geranium robertianum*). The old stages in sites without *R. pseudacacia* in the surroundings were formed by a (semi-) natural wooded grassland.

**Discussion**

Analyses based on species groups, representing different vegetation types, showed a similar pattern of vegetation succession as those based on particular species. Similar conclusions were found also for the role of environmental factors (see details in Rehounková & Prach 2006). This indicates that the groups of species can be used instead of particular species for an outline of succession in restoration programs (Voigt & Perner 2004). However, the scientific basis should be at the species level, because of the assignation of species to groups.

Undesirable ruderal and alien plants can be expected to be of larger importance if a disturbed site is located in heavily altered landscapes such as those composed mostly of intensively used agrarian or urban land (Roy et al. 1999, Prach et al. 2001). The occurrence of ruderals and especially aliens was lower in pits located in less human altered landscapes, which have a higher proportion of forests and are located in wetter and colder regions (see the sub-sere A2); this seems to be a general pattern. The lower importance of ruderals and aliens in uplands and wet sites (seres B and C) corresponds with the fact that more Central European ruderal and alien species require drier and warmer sites than those in the local flora (Pyšek et al. 1995).

Although it has been noted that the surrounding vegetation generally influence succession in post-mining sites (e.g. Roche et. al. 1998, Ninot et al. 2001, Martínez-Ruiz et al. 2001), few quantitative studies have focused on this topic (Borgegård 1990, Brändle et al. 2003). The restoration potential of the surrounding vegetation, influencing the processes of spontaneous vegetation succession in disused pits, is quite high (Fig. 3). A comparably high number of species were found in both the pits and surrounding (semi-) natural vegetation in the case of woodland, grassland and especially wetland species. Alien species were also successful in colonizing the pits. The low proportion of ruderal species was surprising because many are easily dispersed generalists (Grime 2002). It seems that the nutrient-poor environment of the gravel-sand pits is not very favorable for them.

Borgegård (1990) studied the effect of surrounding vegetation represented by different forest types in 68 abandoned gravel pits, ranging in age from 1 to 100 years throughout Sweden, and found that, on average, only about one third (35%) of speci-
cies were shared by gravel pits and their surroundings. About half of the local species pool was found within non-reclaimed lignite mining sites in Germany (Brändle et al. 2003). Recently established forest fragments in Belgium contained 47% of the flora found within a 100 m radius in the neighbouring old forest (i.e. local species pool) (Butaye et al. 2002). It is likely that the target vegetation may be well restored via natural colonization in those disused gravel-sand pits that are adjacent to (semi) natural vegetation, which can act as seed sources for many target species. Long-distance dispersal mostly by epizoochory, besides seed sources in the surroundings, may also be important for the establishment of wetland vegetation (Krahulec & Lepš 1994). If the pit is flooded, it is highly likely that water birds will help the expansion of wetland species into the pit because of bird migration among water bodies across the landscape. In this study, 11 wetland species were found to occur only in the pits and were not observed in the close surroundings; there were no such species among the other groups. If wetlands, including shallow water bodies, occurred in the close vicinity, there was a high probability that the respective species occurred in a pit. This is also related to the frequent short-distance migration of waterfowl (Figuerola et al. 2005).

Alien species may be able to colonize early after a disturbance, interfering with restoration efforts or altering successional processes that would otherwise lead to a native vegetation, which can act as seed sources for many target species. Long-distance dispersal mostly by epizoochory, besides seed sources in the surroundings, may also be important for the establishment of wetland vegetation (Krahulec & Lepš 1994). If the pit is flooded, it is highly likely that water birds will help the expansion of wetland species into the pit because of bird migration among water bodies across the landscape. In this study, 11 wetland species were found to occur only in the pits and were not observed in the close surroundings; there were no such species among the other groups. If wetlands, including shallow water bodies, occurred in the close vicinity, there was a high probability that the respective species occurred in a pit. This is also related to the frequent short-distance migration of waterfowl (Figuerola et al. 2005).

Alien species may be able to colonize early after a disturbance, interfering with restoration efforts or altering successional processes that would otherwise lead to a native assemblage (D’Antonio & Meyerson 2002). In this study, this situation was associated with the dry sere in lowlands, which provided suitable conditions for the alien Robinia pseudacacia. This species can form compact cover and change the course of vegetation succession from the target of shrubby grassland to undesirable Robinia groves. The same was observed in the case of disused stone quarries by Novák & Prach (2003) and by Cleveland & Kjelgren (1994) in deep-tilled minesoil. Robinia pseudacacia is easily dispersed vegetatively and by seeds over a short distance (Halassy 2004, Török & Loháš 2004), and it is, therefore, not surprising that it is able to colonize the sites in gravel-sand pits only if it occurs in their close proximity. The role of R. pseudacacia in succession may be complex, since it also affects litter decomposition, nitrogen fixation and the mineralization rate of other nutrients (White et al. 1988). The effect of R. pseudacacia on species composition of the field layer through nitrogen fixation is likely to be strongest on poor sandy soils where nitrogen is the main limiting soil resource, resulting in a considerable rise in the number and cover of nitrophilous and ruderal herb species (see also Dzwonko & Loster 1997, Török & Loháš 2004).

Fig. 4. CCA ordination of species and successional stages in dry regions, sorted according to the presence (∆) and absence ( ) of generative Robinia pseudacacia in the surrounding vegetation (up to 100 m from a sampling site – see Ai, P < 0.05). The direction of succession is shown using centroids (triangle) for each age group. Increasing size of the symbols corresponds to increasing age: initial (1–3 yr), young (4–10 yr), middle (11–25 yr), late (26–40 yr), old (> 41 yr). Species with weight > 5% were considered. Species abbreviations used are composed from the first four letters of generic and species names.
Differences in nitrogen and light availability are expected to contribute to the strong divergence in the successional development of older stages of the dry sub-sere in lowlands (see also Peloquin & Hiebert 1999). Despite the fact that there are some studies which documented slow colonization of Robinia groves by native tree and woodland herb species in Europe (Hruška 1991, Dzwonko & Loster 1992), no signs of succession from Robinia groves to woods dominated by native tree species were observed in the gravel-sand pits, as well as in other disturbed sites, in the Czech Republic.

The successional trends are summarized and generalized in Table 2, in regards to site moisture and geographical location (being related to macroclimate). It is obvious from the table that site moisture is the main factor determining the physiognomy of the vegetation and participation of ecological groups of species. Macroclimate is a second predictor only in the case of dry sites, where low soil moisture may be a limiting factor. Naturally, this is not the case in wet and flooded sites where other factors are more important. The peculiarity of spontaneous vegetation succession for restoration of disused gravel-sand pits is also seen from the table, which may be used as a rough guide of succession in restoration programs for particular pits.

### Implications for practice

- Restoration of target vegetation (i.e. grassland, woodland or wetland) in the studied disused gravel-sand pits by processes of spontaneous vegetation succession can be successfully achieved in about 20 years. Thus, no technical restoration is needed.
- The presence of (semi-)natural vegetation in the close surroundings facilitates this process; thus it is important to preserve at least some remnants of the vegetation during mining and postmining operations.
- However, the invasion of alien species, such as black locust (*Robinia pseudacacia*) in dry sites in lowlands in this study, must be taken into consideration. Such species should be eradicated in the vicinity of a pit before the onset of succession.

Chapter IV

Life-history traits and habitat preferences of species in relation to their colonization success in disused gravel-sand pits

Řehounková, K. & Prach, K. [manuscript]
Life-history traits and habitat preferences of species in relation to their colonization success in disused gravel-sand pits

Abstract

We used plant life-history traits and habitat preferences by species to find which of the characteristics predict establishment of species in different successional stages inside the disused gravel-sand pits.

Data were collected in 36 abandoned gravel-sand pits in various regions of the Czech Republic. Seral stages in the gravel-sand pits ranged in age from 1–75 years. Together 224 phytosociological relevés were recorded in 5 m x 5 m plots in representative parts of all available seral stages. Complete lists of species occurring in (semi-) natural habitats were surveyed up to the distance of 100 m from each relevé. Colonization success of each species was expressed by an index between 0–1 which was obtained as the ratio: the number of relevés with species present/the number of relevés with the species occurrence in the surroundings. Data were elaborated by the ordination analysis and the regression tree analysis.

Results showed that certain traits were linked with colonization success in three main stages of vegetation succession: young, middle, and late. Generally, the most successful colonisers of disused gravel-sand pits were hydrophytes with ability to vegetative reproduction. At the beginning of succession, the most important role played anemochorous, stress tolerant species, possessing light diaspores, being typical for nitrogen poor and acid habitats. Later, the importance increased of sciophyous and nitrophilous species of mesic habitats, with heavier diaspores, mostly phanerophytes or geophytes, often with ability to vegetative reproduction and higher demands for pH. Probability of species occurring in the surroundings to colonize gravel-sand pits is decreasing in succession: young stages – 41 %, middle stages – 30 %, late stages – 15 %.

Synthesis and application

Plant functional traits were recognized as powerful tools to predict colonization success of plants available in the local species pool. It may help in prediction of vegetation succession in various human-disturbed sites and thus be used in various restoration programmes.
Introduction

There is an increasing interest in using species’ traits, and the grouping of species by their traits into functional types, to predict vegetation responses to environmental factors or human activities, such as climate (Díaz & Cabido 1997), disturbance (McIntyre et al.1999; Lavorel et al. 1997), land-use (Lloret & Montserrat 2003; Verheyen et al. 2003), ecological restoration (Pywell et al. 2003) or grazing (de Bello et al. 2005). The concept of ecological succession often underpins the studies (Walker & del Moral 2003). Relatively little is known how successfully established species on newly created sites differ in their biological and ecological traits from those which do not play an important role in vegetation succession (Rydin & Borgérząd 1991; Prach & Pyšek 1999).

Dispersal of diaspores into newly created habitats, especially if a viable seed bank is lacking, may be considered as a key process for the establishment of vegetation (Bakker et al. 1996). How many and which species ultimately will be able to reach such habitats by their diaspores depends on characteristics of the diaspores, availability and behaviour of the transporting vectors, and the composition, abundance and proximity of the local seed sources (Díaz et al. 1998; Yao et al. 1999; Nathan & Muller-Landau 2000; Ozinga et al. 2005). Beside dispersal itself, other reproductive characteristics, such as germination and vegetative spread, and ecological demands of species are usually considered to determine colonization success of species during succession (van der Valk 1992). Integral categories such as life-forms and life-history strategies may be good predictors of species colonization success (Grime 2001). Local site factors act as selective filters of the species possessing different traits (Bazzaz 1996). Thus, a joint analysis of species and habitat characteristics may increase prediction of species success which may have, besides theoretical, also practical implications especially in restoration ecology (van Andel & Aronson 2006).

In previous studies, we analysed role of local site and landscape factors in the course of spontaneous vegetation succession in disused gravel-sand pits over a broader geographical scale (Rehounková & Prach 2006; Rehounková & Prach 2007). In the present paper, we attempted to define trait-based groups of plant species occurring in the close surrounding of disused gravel-sand pits in relation to their colonization success inside the pits. We considered in our study a short-distance dispersal, which was arbitrarily defined as dispersal up to 100 m distance following Cain et al. (2000). Considering dispersal may allow prediction and generalization of vegetation changes in disturbed sites in a landscape scale (Verheyen et al. 2003).

The ordination and regression tree analyses were used to express relationships between species traits and habitat preferences and the colonization success of the species. The following main questions were asked: Species of what traits and ecological demands are successful/ unsuccessful colonizers of disused gravel-sand pits? How do the traits differ among species successful in differently aged successional stages?

Methods

Study area

The study was conducted in gravel-sand pits spread over the Czech Republic, Central Europe (48°30’ – 51°00’ N; 12°00’ – 18°50’ E) in 2002-2004. The altitude of the studied pits ranged from 170 to 540 m a.s.l. The history of each pit was reconstructed on the basis of official records from mining companies and county authorities and by interviewing local administrators. The pits and representative disused sites in each of them were selected using the following criteria: (1) the existence of sufficiently large, spontaneously re-vegetated sites, (2) the year of abandonment was known, (3) no evidence of allochtonous substrates, (4) no evident additional disturbance. 36 pits in the entire country were those which matched the criteria. The period since abandonment (age) ranged from 1 to 73 years among the particular sites. Three main successional stages were distinguished according to age: young (1–10 yr), middle (11–20 yr) and late (21–75 yr).

The pits were classified according to their location in either (a) lowlands (altitude 170 – 250 m a.s.l.) having a relatively warm and dry climate (mean annual temperature 8.0–9.2 °C, precipitation 480 – 550 mm), and used mostly for agrarian purposes, or (ii) uplands (altitude 255–540 m a.s.l.) having a relatively cold and wet climate (mean annual temperature 6.8–7.9 °C, mean annual precipitation 551–780 mm) and dominated by woodland. All of the sites developed on sandy and gravelly deposits originated from eolic and fluvial processes in the Quaternary period. The pit area ranged from 1 to 95 ha.

Sampling

Differently aged successional stages were distinguished in each pit and phytosociological relevés (5 x 5 m) were recorded in the centre of each of the stages (for details see Rehounková & Prach 2006). For the purpose of this study, a species list was considered for all relevés of the respective successional stage, i.e. young, middle, and late. Species which attained dominance at least 1% at least in one relevé were considered as successfully established in the respective successional stage. The surrounding (semi-) natural vegetation, i.e. not influenced by mining and reclamation activities – woodland, grassland, wetland, occurring up to 100 m from each relevé was surveyed and all vascular plant species were recorded. We considered only species occurring in (semi-) natural vegetation which was expected to exist before mining started and which is the most relevant from the point of view of restoration of a site. Thus, we neglected species often of the same seral stage which would bias the next calculations.

Data elaboration

Colonization success was expressed as an index between 0–1. It was calculated for each species separately and expressed as the ratio: number of relevés in which the species was present/number of relevés with the species occurrence in (semi-) natural vegetation in the surroundings.
Altogether seven basic life-history traits and five habitat preference characteristics based on the Ellenberg indicator values for light, moisture, nitrogen and soil reaction (Ellenberg et al. 1992) were considered (see Table 1). The information was compiled from available databases and other relevant sources: Klotz et al. (2004), Grime et al. (1988), Ellenberg et al. (1992), Bonn et al. (2000), Jackel et al. (2006), and Tackenberg et al. (unpublished).

The habitat preferences were grouped each into three categories as evident from Table 1. The degree of hemeroby was grouped into the category of habitats (Klotz et al. 2004). Habitat type: Natural – species of very weakly utilized woodlands, near-natural dry grasslands or wetlands; (Semi-)natural – species of utilized forest with well developed shrub and herb layer, slightly utilized pastures and meadows; (Semi-)cultural – species of intensely used pastures, meadows or forest with little developed shrub and herb layer; Cultural – species of arable fields with typical weed communities, ruderal sites (e. g. landfills). Traits and habitat preference characteristics were categorized by means of fuzzy coding, i.e. the species can belong to several classes of one trait at the same time. For example, species, which can disperse by anemochory and zoochory would have a score 0.5 as anemochorous and 0.5 as zoochorous with the total sum 1 for the trait dispersal.

Two approaches were applied to evaluate which species characteristics are related to the colonization success of species in the course of succession: the ordination analysis (CANOCO, ter Braak & Šmilauer 2002) and the regression tree analysis (R software, R Development Core Team 2004). In ordination, the Canonical Correspondence Analysis (CCA) was carried out with the only significant explanatory variable, i.e. age (years since the site abandonment). The score of species on the ordination axis was used as the species response to the age of site. In the second step, the Detrended Correspondence Analysis (DCA) was performed. The traits and habitat characteristics were used as a “species” data. The species response to the successional age, obtained by CCA, and the colonization success of species were fitted ex post as passive variables (Lepš & Šmilauer 2003).

The regression trees provide an alternative to regression techniques (Vayssières et al. 2000). The tree is built by repeatedly splitting the data, defined by a simple rule based on a single explanatory variable. At each split, the data are partitioned into two exclusive groups, each of which is a homogeneous as possible. The length of the tree was controlled by choosing the best trade-off between explained deviance and tree size through cross-validation procedure. Pruning the trees was applied (Venables & Ripley 2002; Thuiller et al. 2003). The regression trees are used as a suited tool for analyses of rather robust ecological data, but only rarely used to predict vegetation succession (e.g., de Bello et al. 2005). The regression tree approach allows the visualization of hierarchical trait combinations and the effects are usually non-additive (De Patta & Sosinski 2003).

Results

In total, 624 vascular species were recorded in the gravel-sand pits and their surroundings. Eight species occurred only in pits while 194 only in the surroundings. That means, about two-thirds of the species occurring in the surroundings appeared in the course of succession also inside the pits. The proportion of newly established species decreased with successional age (Table 2). The proportion of remaining species not yet established in the previous stages, calculated from the total number of species in the surrounding for each stage, decreases about one-third during the succession (Table 2).

Probability to colonize gravel-sand pits by species from the surroundings decreased during succession: young stages – 41 %, middle stages – 30 %, late stages – 15 %.

The indirect ordination analyses showed which life-history traits and habitat characteristics are important for successful colonization of disused gravel-sand pit in the course of succession (Fig. 1). The eigenvalues of the first and second axis were 0.6 and 0.49 respectively. In general, the most successful colonizers were hydrophytes possessing ability to vegetative reproduction. In the young stages, the most successful colonizers were anemochorous stress tolerant species, growing on nitrogen poor and acid sites. The unsuccessful colonizers of these stages are characterized as disturbance tolerant species (R-strategists) typical of arable fields and ruderal sites reproduced exclusively by seeds, mostly therophytes. In the late stages, competitive, sciophilous and wind pollinated species typical of (semi-)natural habitats possessing vegetative reproduction, mostly hydrophytes or geophytes of mesic and wet sites are favoured. The unsuccessful colonizers of late stages are predominantly insect pollinated, nitrophyllus phanerophytes typical for sites intensively altered by humans.

Results of the regression tree analyses basically corresponded to DCA ordination. In the regression trees we visualized also the combination of particular life-history traits and habitat preference characteristics in three different successional stages – young, middle and late (Fig. 2).

The most successful colonizers in the young stages (1–10 years) were either moisture demanding species with light diaspores (colonization success – 52 %) or if not moisture demanding species than macrophanerophytes with light seeds (63 %) and if not macrophanerophytes than non-insect pollinated heliophilous species with light diaspores (41 %). The least successful colonizers of the young stages are sciophilous non-macrophanerophytes, with light diaspores growing on dry or mesic sites (4 %) – Fig. 2a.
The most successful colonizers in the middle stages (11–20 years) are either hydrophytes (69%) or if not hydrophytes than wind pollinated species typical of (semi-)natural habitats with intermediate demand for nitrogen (30%). The unsuccessful colonizers of these stages are either wind pollinated anemochorous species with intermediate demand for nitrogen (6%) or if not anemochorous species than species typical of habitats with either very high or rather low level of naturalness (4%) – Fig. 2b.

The most successful colonizers in the late stages (> 21 years) are either insect pollinated species of natural habitats less exhibiting C-strategy (33%) and if competitive species, than there are autochorous (20%). The unsuccessful colonizers of these stages are either species typical of human-altered habitats (5%) or if not than insect pollinated not competitive and not autochorous species of natural habitats – Fig. 2c.

Discussion

Vegetation changes at all scales are governed by both dispersal limitation, and the ability of species to establish and persist (Pywell et al. 2003). Life-history traits adaptive to different conditions are likely to be inversely correlated (Duckworth et al. 2000). Therefore, those that are important in early succession are less likely to be
important in late successional stages and *vice versa*. Our results were mostly consistent with this pattern.

The DCA ordination provided non-hierarchical combinations of species related to colonization success of species and successional time, while the regression trees considered hierarchy of traits (Thuiller et al. 2003). This may cause some differences obtained by both methods. For example, autochory appeared to be important in late stages only in the case of insect-pollinated, C-strategists being typical for natural habitats, while in the DCA ordination diagram autochory appeared to be negatively correlated with time and neutral to the colonization success. Similarly, insect pollination, though related to late successional stages and being negatively related to species success in the ordination, appeared an important trait in early successional stages but only in the case of heliophillous species of dry and mesic sites possessing light diaspores. This justifies using both methods.

Species colonizing particular successional stages (young, middle, late) of disused gravel-sand pits exhibited different combinations of traits in terms of life-history traits and habitat preferences. Initial success was related to traits which determine colonization ability of the species, such as anemochory and production of light diaspores, whereas persistence-related traits, such as vegetative reproduction and high competitive ability, increased in importance in time (Pakeman 2004). Our results are mostly consistent with theoretical expectations (Glenn-Lewin et al. 1992; Grime 2001), however, there are some trends which differ. Progressive replacement of therophytes by hemicyryptophytes, chamaephytes, and phanerophytes during succession on man-made sites has been repeatedly reported (Prach et al. 1997; Vile et al. 2006). We found chamaephytes to be often successful in the young stages while therophytes were unsuccessful in general. It may be attributed to the nutrient poor, acid site conditions on bare sand or gravel for which species from the families Ericaceae and Vacciniacae are typical (Grime et al. 1988, Ellenberg et al. 1992). The bare sand and gravel seem to provide rather adverse conditions for fast growing ruderals. Similarly, the transition from R-strategists to C- and S-strategists is usually prevailing during succession (Grime 2001; Osbornová et al. 1990), however in our case S-strategists belonged to the species with the highest colonization success in the young stages. R-strategists also spread into the gravel-sand pits mostly at the beginning of succession but they usually did not expand too much. It is obvious, the succession on nutrient poor and acid sites has some specific features (Tilman 1988). The increase of the former ones can be explained by the fact that many species typical of initial stages of succession do not possess specific modes of dispersal.

There is usually expected a shift from high prevalence of wind dispersal of light seeds in the early successional stages to the high prevalence of zoochory and autochory in mature stages of succession (Rydin & Borgegård 1991; Wiegmann & Waller 2006) as small seeds are generally advantageous for long-distance dispersal, whereas larger seeds have a greater possibility of germinating and establishing in closed vegetation (Schippers et al. 2001; Verheyen et al. 2003). In our case, both anemochory and zoochory, and also hydrochory, were more or less neutral to the successional age (Fig. 1). It may be explained by some earlier findings that first colonizers possess hea-
Conclusions and applications
1. The most successful colonizers of the disused gravel-sand pits are hydrophytes with ability to vegetative reproduction. The least successful are annual weeds and ruderals.
2. Species typical of natural vegetation are largely successful, most in the late stages.
3. In young stages, the most important role play the anemochorous, stress tolerant perennial species with light diaspores, typical for nitrogen poor and acidic habitats.
4. The importance of scio- and nitrophilous species of mesic habitats, with heavier diaspores, mostly phanerophytes or geophytes, often with ability to vegetative reproduction and preferring less acidic sites increase with age.
5. Probability of species to colonize gravel-sand pits from the surroundings is decreasing in succession: young stages - 41 %, middle stages - 30 %, late stages - 15 %.
6. Plant functional types can be a useful tools in predicting colonization success of species occurring in the surrounding (semi-)natural vegetation into disused gravel-sand pits and this may be potentially exploited in various restoration programmes.

Spontaneous vegetation succession and the effect of abiotic factors in a disused gravel-sand pit

Řehounková, K. & Prach, K. [manuscript]
Spontaneous vegetation succession and the effect of abiotic factors in a disused gravel-sand pit

Abstract

Variability of vegetation development and the relative importance of abiotic factors influencing spontaneous vegetation succession were studied in a disused gravel-sand pit in the eastern part of the Czech Republic (central Moravia). The study site was 2 ha and gravel and sand extraction was stopped in 1982. Four types of sites habitats were distinguished: mesic, wet, shallow flooded and aquatic. Vegetation relevés were recorded in 34 permanent plots (4 m x 1 m). Semiquantitative cover of all vascular species and bryophytes was estimated by the seven point Braun-Blanquet scale. The vegetation samples were repeated between 1997 and 2005, that is 1, 2, 3, 4, 5 and 8 years since the extraction was stopped. Abiotic factors, such as water table and soil physical and chemical characteristics, were evaluated. Ordination analysis showed that, after eight years, vegetation development led to the formation either of mesic grassland with scattered shrubs, Salix carrs accompanied by Phragmites australis, Typha latifolia and P. australis or macrophyte vegetation in pools depending predominantly on site moisture conditions. Water table was the factor most influencing spontaneous vegetation development. Vegetation succession was further significantly influenced by other abiotic factors, namely soil texture and pH.

The vegetation development and changes in abiotic factors, though observed for only the first 8 years of succession, showed similar trends as those resulting from a broad-scaled and multi-site study of gravel-sand pits throughout the Czech Republic.

Introduction

The excavation of gravel and sand in large pits, necessitating the removal of topsoil, has created large areas completely devoid of vegetation and diaspores (Borgegård
1990). In spite of the fact that such sites are quite frequent in various landscapes, detailed or long-term studies on spontaneous vegetation succession in disused gravel-sand pits are very rare (Borgegård 1990, Rehounková & Prach 2006). Unfortunately, these sites are often technically reclaimed to large water bodies or planted with conifers, eventually reclaimed for agrarian use. For ecologists, the disused gravel-sand pits represent suitable sites for research on succession as processes of primary succession hardly ever can be observed elsewhere in the European cultural landscape except mining sites (Glenn-Lewin, Peet & Vehlen 1992). Moreover, such sites provide a challenge for conservation biology, providing refugia for rare and retreating species or wetland formation (Rehounková & Prach 2007).

Restoration ecology involves the development of structural or functional characteristics of ecosystems that have been lost (van Andel & Aronson 2006). It includes habitat creation that may aim to establish plant communities that are representative of the original, undamaged state. Many restoration projects are implemented as mitigation for the loss of natural wetlands resulting from the development of cultural ecosystems. However, spontaneous succession often provides desirable target ecosystems better than technical reclamation (Prach 2003). Distinguishing which factors most influence the development of a plant community is crucial for successful ecosystem restoration. The use of permanent plots is the best method to study long-term changes in vegetation (Bakker et al. 1996).

The main objective of this study was to relate the course of spontaneous vegetation succession in the restored part of a gravel-sand pit to abiotic factors during the first eight years after site creation. The questions addressed in this paper are: What is the variability of spontaneous vegetation succession in a disused gravel-sand pit? Which abiotic and environmental factors potentially influence vegetation succession?

Study area

The Nature Reserve Chomoutov lake (4 km north from the town of Olomouc – 49° 40’ N, 17° 15’ E) is part of a Protected Landscape Area situated in the eastern part of the Czech Republic (central Moravia). The southern part of the studied gravel-sand pit was surveyed from 1998 to 2005. The following habitats were arbitrarily distinguished in the pit according to site moisture prior to the following analyses: mesic (water table 1–2 m below the surface), wet (water table 0–1 m below the surface), shallowly flooded sites (0.05–0.2 m above the surface) and aquatic (more than 0.2 m above the surface). A total of 34 permanent plots was established in the site with topsoil removed in 1998 in all habitat types (dry, wet, shallow flooded and aquatic). The plots were fixed by an inserted metal square plate with a spike in each corner. A wooden peg (height 1 m above the surface) was inserted near each metal plate to find the plot easier. Horáková (1999) recorded the vegetation in 1 m x 4 m permanent plots in the first year of succession (1998) in a water ditch, habitats with water table 0–2 m below the surface and in the larger water body. Therefore, the methodology used by Horáková (1999) was respected to describe the vegetation succession from the beginning. Phytosociological relevés were recorded in each of the permanent plots at the end of July and beginning of August during the 1st, 2nd, 3rd, 4th, 5th and 8th year after site restoration. In this way, 204 relevés were obtained. Semi-quantitative cover, defined by the seven point Braun-Blanquet scale, was estimated for vascular plants in each relevé (Kent & Coker 1992).

Water table depth was measured in a bore hole on the margin of each relevé. In total, 20 measurements were conducted during the six studied vegetation seasons from 1997 to 2005. The inclination of all sites where the relevés were recorded was 0º–5º. Therefore, inclination was not considered further as an explanatory variable.

Soil samples were collected in all studied years, i.e. 1998, 1999, 2000, 2001, 2002 and 2005. Four subsamples of the first 0.3 m below the organic layer of the top soil were taken from margins of each relevé and mixed into one pooled sample. The samples were analysed for pH, texture, total nitrogen, organic carbon (Zbíral 1997), phosphorus, potassium, calcium, magnesium and electric conductivity (Antanasopoulos 1990). Soil texture was determined by wet sieving and a Fritsch Scanning-Foto-Sedimentograf for determination of particles smaller than 0.05 mm. Percentage weight of particular soil fractions followed the United States Department of Agriculture (USDA) standard method (gravel: particles > 2 mm, sand: 2–0.05 mm, silt: 0.05–0.002 mm and clay: < 0.002 mm).

Data analysis

Vegetation and abiotic data were analysed using multivariate methods in CANOCO version 4.5-4. (ter Braak & Šmilauer 2002). A unimodal relationship between species occurrence and time was expected, thus Detrended Correspondence Analysis (DCA) and Canonical Correspondence Analysis (CCA) were used. The length of the DCA gradient was 6.63 SD. Species data were not transformed. In DCA, detrending by segments was used and species with a weight of at least 5% were shown. In CCA, inter-sample distance and Hill scaling were used. Abiotic data were fitted ex post to the

Methods

Sampling

The gravel-sand pit was surveyed from 1998 to 2005. The following habitats were arbitrarily distinguished in the pit according to site moisture prior to the following analyses: mesic (water table 1–2 m below the surface), wet (water table 0–1 m below the surface), shallowly flooded sites (0.05–0.2 m above the surface) and aquatic (more than 0.2 m above the surface). A total of 34 permanent plots was established in the site with topsoil removed in 1998 in all habitat types (dry, wet, shallow flooded and aquatic). The plots were fixed by an inserted metal square plate with a spike in each corner. A wooden peg (height 1 m above the surface) was inserted near each metal plate to find the plot easier. Horáková (1999) recorded the vegetation in 1 m x 4 m permanent plots in the first year of succession (1998) in a water ditch, habitats with water table 0–2 m below the surface and in the larger water body. Therefore, the methodology used by Horáková (1999) was respected to describe the vegetation succession from the beginning. Phytosociological relevés were recorded in each of the permanent plots at the end of July and beginning of August during the 1st, 2nd, 3rd, 4th, 5th and 8th year after site restoration. In this way, 204 relevés were obtained. Semi-quantitative cover, defined by the seven point Braun-Blanquet scale, was estimated for vascular plants in each relevé (Kent & Coker 1992).

Water table depth was measured in a bore hole on the margin of each relevé. In total, 20 measurements were conducted during the six studied vegetation seasons from 1997 to 2005. The inclination of all sites where the relevés were recorded was 0º–5º. Therefore, inclination was not considered further as an explanatory variable.

Soil samples were collected in all studied years, i.e. 1998, 1999, 2000, 2001, 2002 and 2005. Four subsamples of the first 0.3 m below the organic layer of the top soil were taken from margins of each relevé and mixed into one pooled sample. The samples were analysed for pH, texture, total nitrogen, organic carbon (Zbíral 1997), phosphorus, potassium, calcium, magnesium and electric conductivity (Antanasopoulos 1990). Soil texture was determined by wet sieving and a Fritsch Scanning-Foto-Sedimentograf for determination of particles smaller than 0.05 mm. Percentage weight of particular soil fractions followed the United States Department of Agriculture (USDA) standard method (gravel: particles > 2 mm, sand: 2–0.05 mm, silt: 0.05–0.002 mm and clay: < 0.002 mm).

Data analysis

Vegetation and abiotic data were analysed using multivariate methods in CANOCO version 4.5-4. (ter Braak & Šmilauer 2002). A unimodal relationship between species occurrence and time was expected, thus Detrended Correspondence Analysis (DCA) and Canonical Correspondence Analysis (CCA) were used. The length of the DCA gradient was 6.63 SD. Species data were not transformed. In DCA, detrending by segments was used and species with a weight of at least 5% were shown. In CCA, inter-sample distance and Hill scaling were used. Abiotic data were fitted ex post to the
DCA ordination axes as passive variables (ter Braak & Šmilauer 2002). To show the effect of successional changes, the identifier of relevés (coded as several dummy variables) was used as a covariable in the analyses. Besides successional age, the following abiotic factors were used (Table 1): water table, texture expressed as the percentage of soil fraction weights, pH, total nitrogen, organic carbon, phosphorus, calcium, magnesium, potassium and electric conductivity.

Forward selection was conducted with all abiotic factors (Table 1). Variance Inflation Factors (VIFs) were below 3, indicating a low correlation of variables (ter Braak & Šmilauer 2002). Subsequent analyses contained only the significant factors (P < 0.05). Within the CCA analyses, combining the factors and covariables followed by the Monte Carlo permutation test (i.e. 999 permutations), allowed for the testing of the partial effect (denotes the variability explained by a given environmental variable considering the effects of other environmental factors, i.e. covariables) of abiotic factors. Marginal effects (denotes the variability explained by given environmental variables without considering other environmental factors) in CCA were also calculated with CANOCO and tested for significance with the Monte Carlo permutation test (i.e. 999 permutations).

Results

Species pattern

Altogether, 130 species were recorded in the permanent plots during the eight years. Vegetation development differed depending on the habitat type, resulting in four successional series: A) mesic, B) wet, C) shallow flooded and D) aquatic (Fig. 1b). Species turnover is clearly seen in all successional series, except the aquatic one (Fig. 1a). Aquatic species, such as Myriophyllum spicatum, Ceratophyllum demersum and Lemna minor, dominated in the aquatic serie in each year of the eight year succession. Because no significant species turnover appeared, the aquatic serie was not further described in details as the other series (Fig. 1a).

A sparse cover of annual species was characteristic for the dry habitats in the first year. In the second year, perennials (e.g. Agrostis stolonifera, Erophila verna, Lactuca serriola, Medicago lupulina, Spergularia rubra, Plantago lanceolata, Deschampsia cespitosa, P. palustris, Poa annua, Rumex thyrsiflorus, Juncus articulatus) and biennials (e.g. Capsella bursa-pastoris, Capsella orientalis, Cirsium arvense, Galium album, Plantago lanceolata, Deschampsia cespitosa, P. palustris, Poa annua, Rumex thyrsiflorus) were frequent in wet and shallow flooded habitats. Agrostis stolonifera and Cirsium vulgare were frequent in wet and shallow flooded habitats.

The proportion of perennial grassland herbs and graminoids and ruderal species decreased in the fourth year. Grassland species, such as Lotus corniculatus, Achillea millefolium, Plantago lanceolata, Deschampsia flexuosa and Poa palustris, were typical for mesic habitats, while wetland species, such as Allium plantaegoscapa, Eleocharis palustris, Phragmites australis occurred in shallow flooded habitats. The first pioneer trees and shrubs appeared in dry (Betula pendula) and wet (Salix purpurea, S. viminalis, S. cinerea) habitats. Calamagrostis epigejos started to expand both in mesic and wet habitats.

In the following year (5), vegetation composition in all habitats reflected the successional trends from the previous year. Perennial species, such as Galium album and Vicia tetrasperma, were accompanied by scattered woody species (Betula pendula, Populus x canadenensis) in mesic habitats. Tenaciotum vulgar was the only ruderal species markedly presented in mesic habitats. Gradually, woody species (Salix caprea, S. fragilis, Populus alba) expanded into the wet habitats. Wetland species cover, especially Typha latifolia, increased in shallow flooded habitats.

After eight years, the mixture of perennial herbs and grasses, with the first scattered shrubs (Rosa canina, Rubus caesius) and trees (Betula pendula, Populus x canadenensis), domi-
nated in the mesic habitats. The relatively closed herb layer was formed by grassland species (e.g. *Potentilla reptans*, *Potentilla argentea*, *Hypericum perfoliatum* and *Elytrigia repens*) in the mesic habitats. The woody species composition in wet habitats formed open willow carrs (e.g. *Salix alba*, *S. caprea*, *S. fragilis*, *S. cinerea*) accompanied by *Phragmites australis* in the understory. Wetland species (e.g. *Typha latifolia* and *Phragmites australis*) formed a relatively closed herb layer in shallow flooded habitats.

**Abiotic factors determining vegetation succession**

Significant abiotic factors included water table level, all four particular soil fractions and pH, while seven factors were found not to significantly influence vegetation variability during the first eight years of vegetation succession (Table 1). Only the DCA graphical outputs are displayed (Fig. 1), because of the similarity with the CCA ordination results demonstrated by the high values of species-environment correlations on the first DCA and CCA axes (Table 2). The CCA analyses found that 74.7% of variability was explained by seven environmental factors (Table 2). Both partial and marginal effects of each of the six abiotic factors and age were significant (Table 3).

The importance of abiotic factors and age, influencing the processes of spontaneous vegetation succession in the disused pit, is shown in Fig. 1a (inset diagram). Water table was positively correlated with the first axis and explained the largest amount of vegetation variability, i.e. 28.4% (partial effect). The second axis was positively correlated to site age and explained 14.7% (partial effect) of vegetation variability. Fine-grained substrates, with higher amounts of clay and silt particles, were related to wetter habitats and increased with time, while coarse-grained substrates formed by sand and gravel particles prevailed in mesic habitats. The pH increased with age.

Fig. 1a. DCA species ordination. The inset figure shows the DCA ordination of significant environmental factors (P<0.05, Table 1) fitted ex post as passive variables. The species with weight >5% were considered. Species abbreviations used are composed of the first four letters of the generic and species names.
Species composition changing during succession is influenced by local site factors, such as abiotic characteristics, disturbance and species interactions, and landscape factors such as macroclimate, the species pool and land-use history (Walker & del Moral 2003).

The course of spontaneous vegetation succession in the restored part of the gravel-sand pit differed due to variable moisture conditions. We found a diverse mosaic of vegetation on each four habitat types, while further vegetation development proceeded only in three of the habitats (mesic, wet and shallow flooded). The three major successional series (i.e. mesic, wet, shallow water) clearly differed also within the broad-scaled study of gravel-sand pits (Rehounková & Prach 2006). On the other hand, it appears that the species composition of the aquatic habitat did not show any successional trends in species pattern. The aquatic plants present appeared as early as in the third year (Wiegleb & Felinks 2001). It is clear that on the one hand of the moisture gradient, i.e. in flooded sites, woody species did not have a chance to establish (Prach & Řyšek 1994). The competitive grass Calamagrostis epigejos can arrest further establishment of grassland species and shrubs by forming monodominant compact swards (Prach & Řyšek 2001) and change the course of vegetation succession in dry sites. Both anemochorous seed dispersal from the close surroundings and subsequent vegetative propagation are responsible for the expansion of C. epigejos in such sites (Rebele & Lehmann 2001). Wet and flooded sites are dominated mostly by specialists (Pietzsch 1996), i.e. mostly graminoids, while also woody species in wet sites.

Hydrologic variables have been broadly found to be important abiotic factors influencing the pattern of vegetation (e.g. De Steven & Toner 2004, Ashworth et al. 2006). In this study, the moisture gradient was the most important of all environmental factors. Moreover, it probably masked the effect of time on vegetation development. Time explained only ca. 15% of the vegetation variability in the data set in contrast to moisture (i.e. water table), which was responsible for ca. 28%. This corresponds to evidence from the broad-scaled study of gravel-sand pits throughout the Czech Republic, but the differences in variability explained by the factors was more marketable in the present study site (Rehounková & Prach 2006).

Geology and hydrogeology play important roles in the relationship between species pattern and abiotic factors (especially the hydrologic regime) in the studied site that was influenced by gravel-sand pits extraction and following site restoration. The proportion of the fine-grained and coarse-grained fractions is an important factor influencing availability of soil water, which is important during the whole vegetation season (Havlíček et al. 1996). The relationship between size of soil particles and site moisture was documented also from the broad scaled study of gravel-sand pits, where texture explained ca. 4% of vegetation variability (Rehounková & Prach 2006). This is six times less than in our study. This is probably due to only two soil factions (i.e. gravel, silt) being significant in the broad scaled study.

The influence of pH on community development has been found in studies on created or restored sites (Borgegård, 1990, Ashworth et al. 2006). Soil pH increased with...
time and explained ca. 4% of vegetation variability, which is similar to the 6% found in the broad-scaled study of gravel-sand pits (Řehounková & Prach 2006).

The other soil characteristics, i.e. total nitrogen, phosphorus, organic carbon, magnesium, calcium, potassium and electric conductivity, did not show any significant influence on vegetation development during the eight years of succession, probably because of the small range of their absolute values (Jongman et al. 1987).

We are aware that the observation time (8 years) was short to analyse a full sequence of successional seres, but some successional trends in young (1–3 years) and early (4–8 years) stages were recognized. This study showed that spontaneous vegetation succession proceeds relatively fast towards (semi-) natural vegetation shortly after abandonment of restored gravel-sand pits, i.e. to grasslands with scattered shrubs in mesic habitats, Salix carrs accompanied by Phragmites australis in wet habitats, Typha latifolia and P. australis in shallow water habitats or macrophyte vegetation in pools. Site moisture was the most influential abiotic factor on the course of succession, but it was further influenced by other abiotic factors (i.e. texture, pH). However, a more detailed analysis of landscape factors and their role during early vegetation succession will be necessary to evaluate the restoration project.

References

Conclusions
The review of 37 studies on vegetation succession over a broader geographical scale, started on bare ground in various disturbed sites over the globe, showed that environmental factors have a significant influence on vegetation development. Besides time, i.e. successional age, landscape factors, namely surrounding vegetation and macroclimate, and some local site factors, i.e. soil moisture, amount of nitrogen and soil texture, had the highest influence on the course of succession. Organic content, pH, phosphorus content and size of a disturbed site are local site factors, which have significant effects only in some cases. Surrounding vegetation exhibited a significant effect in all cases whenever this was considered. The results imply that spontaneous succession in various types of disturbed sites, including mining sites such as gravel-sand pits, cannot be studied without a broader landscape context (Chapter I).

At the country scale, spontaneous vegetation succession in gravel-sand pits led to the formation of either shrubby grassland in dry sites in lowlands, deciduous woodland in dry upland sites, alder and willow carrs in wet sites, regardless of region, and tall sedge or reed and cattail beds in shallow flooded sites disregarding the region (Chapter II and III). Except for some dry sites in lowlands, where the alien species Robinia pseudacacia may expand, succession proceeds towards (semi-)natural vegetation within approximately 20 years (Chapter III). Site moisture was the most influential factor on the course of succession. The vegetation pattern was further significantly influenced by the following studied factors: pH and the proportions of silt and gravel among local site factors, and altitude, mean annual temperature, mean annual precipitation, presence of some vegetation types up to 100 m from a sampling site, and predominant land cover up to 1 km from a pit. Although the water table was the most influential on the course of vegetation succession, the landscape factors together explained more vegetation variability (44%) than local site factors (23%) (Chapter II).

Restoration of target vegetation, i.e. grassland, woodland or wetland, in the studied disused gravel-sand pits by processes of spontaneous vegetation succession can be successfully achieved in about 20 years. This means that no technical restoration is needed. The presence of (semi-) natural vegetation in the close surroundings facili-
tates this process; thus it is important to preserve at least some remnants of the vegetation during mining and postmining operations. However, the invasion of alien species, such as black locust (*Robinia pseudacacia*), in dry lowland sites in this study, must be taken into consideration. Such species should be eradicated in the vicinity of a pit before the onset of succession (Chapter III).

Plant functional types can be a powerful tool in predicting colonization success of species occurring in the surrounding (semi-)natural vegetation into disused gravel-sand pits. This may help in the prediction of spontaneous vegetation. It was documented that different traits were linked with colonization success in three main stages of vegetation succession: young, middle, and late. Generally, the most successful colonizers of disused gravel-sand pits were hydrophytes with the ability to vegetatively reproduce, while the least successful were annual weeds and ruderals. Moreover, species typical of natural vegetation are largely successful, mostly in the late stages. The anemochorous, stress tolerant species, with light diaspores typical for nitrogen poor and acid habitats, played the most important role at the beginning of succession. Later, the importance of sciophylous, nitrophilous species of mesic habitats with heavier diaspores, increased. These species are mostly phanerophytes or geophytes, often with the ability to reproduce vegetatively and higher demands on pH. The probability to colonize gravel-sand pits by species from the surroundings decreases during succession: young stages (41% of species appeared in a pit), middle stages (30%), late stages (15%) (Chapter IV).

Vegetation development and changes in abiotic factors, though observed on permanent plots for only the first 8 years of succession in only one extensive pit, showed similar trends as those resulting from a broad-scaled and multi-site study of gravel-sand pits throughout the Czech Republic using the space-for-time substitution approach. Spontaneous vegetation succession proceeded relatively quickly towards (semi-)natural vegetation shortly after abandonment of the restored gravel-sand pit, i.e. to grasslands with scattered shrubs in mesic habitats, willow carrs accompanied by *Phragmites australis* in wet habitats, *Typha latifolia* and *P. australis* in shallow water habitats or macrophyte vegetation in pools over the eight years. Site moisture was the most influential abiotic factor on the course of succession, but succession was further significantly influenced by other abiotic factors, such as texture and pH (Chapter V).

It can be concluded that in many restoration projects potentially scheduled for disused gravel-sand pits, we can completely rely upon spontaneous vegetation succession. Moreover, the disturbed sites provide a challenge for conservation biology, providing valuable biotopes, such as wetlands or open sand grasslands. On the other hand, the negative effects of intensive gravel-sand mining cannot be neglected, such as the destruction of valuable habitats or the presence of monotonous coniferous monocultures resulting from traditional technical reclamation of the pits.
